# Load Calculation Applications Manual 

 Second EditionI-P Edition

This publication was supported by ASHRAE Research Project RP-1616 and was prepared under the auspices of TC 4.1, Load Calculation Data and Procedures.

Results of cooperative research between ASHRAE and Oklahoma State University.

## About the Author

Jeffrey D. Spitler, PhD, PE, is Regents Professor and OG\&E Energy Technology Chair in the School of Mechanical and Aerospace Engineering at Oklahoma State University, where he teaches classes and performs research in the areas of heat transfer, thermal systems, design cooling load calculations, HVAC systems, snow-melting systems, and ground-source heat pump systems. He is also the Fulbright Distinguished Chair of Alternative Energy Technology at Chalmers University of Technology in Gothenburg, Sweden for the 2014-2015 academic year.

He has worked with a wide range of research sponsors, including ASHRAE, the U.S. Department of Energy, the Federal Highway Administration, York International Corporation, and ClimateMaster. He is a past president of the International Building Performance Simulation Association and is an ASHRAE Fellow.

Spitler has served on several ASHRAE technical committees and standing committees. He currently serves on ASHRAE Technical Committee 6.8, Geothermal Heat Pump and Energy Recovery Applications, and the Conferences and Expositions Committee. He has authored or coauthored more than 120 technical papers and six books, including the Annotated Guide to Load Calculation Models and Algorithms.

This manual is the fourth in a series of load calculation manuals published by ASHRAE. The first in the series, Cooling and Heating Load Calculation Manual, by William Rudoy and Joseph Cuba, was published in 1980. A second edition, by Faye McQuiston and myself, was published in 1992 and focused on new developments in the transfer function method and the cooling load temperature difference method. Subsequent to the second edition, ASHRAE Technical Committee 4.1, Load Calculations Data and Procedures, commissioned additional research. This research led to the adaptation of the heat balance method for use in load calculation procedures and development of the radiant time series method (RTSM) as the recommended simplified procedure. Both methods were presented in the third volume of this seriesCooling and Heating Load Calculation Principles, by Curtis Pedersen, Daniel Fisher, Richard Liesen, and myself.

The Load Calculation Applications Manual, also sponsored by TC 4.1, builds on the past three, and some parts are taken directly from previous versions. New developments in data and methods have led to numerous revisions. This manual, intended to be more applications-oriented, includes extensive step-by-step examples for the RTSM.

This work, more so than many technical books, represents the work of many individuals, including the following:

- Authors, named above, of the previous three versions
- Numerous ASHRAE volunteers and researchers who have developed material for the ASHRAE Handbook that has now been incorporated
- Members of the Project Monitoring Subcommittee, including Chris Wilkins, Steve Bruning, Larry Sun, and Bob Doeffinger, who have provided extensive comments, guidance, and direction
- My graduate student, Bereket Nigusse, who has developed most of the spreadsheets underlying the examples and whose doctoral research has led to a number of developments in the RTSM that are incorporated into this manual

The contributions of all of these individuals are gratefully acknowledged.
Jeffrey D. Spitler, PhD, PE

## Preface to the Second Edition

To the casual observer, the need for a new load calculation manual may not be self-evident. Yet, changes in lighting and equipment commonly used in buildings require new data, new methods that are more widely applicable have become available, and other newer data have become available since the first edition was originally published in 2008. These new data and methods have been produced by ASHRAEfunded research and by volunteers working on ASHRAE technical committees (TCs). These effort include the following:

- TC 4.1, Load Calculation Data and Procedures, and their contractors (RP-1482) have produced new internal heat gain data for office equipment.
- TC 4.1 and TC 4.5, Fenestration, and their contractors (RP-1311) have developed new methods and data for computing the effects of internal shading on solar heat gains.
- TC 4.1 and TC 5.10, Kitchen Ventilation, and their contractors (RP-1326) have produced a complete new data set on heat gains from kitchen equipment based on experimental measurements.
- TC 4.2, Climatic Information, and their contractors have produced new weather data (RP-1613) for over 6000 stations worldwide based on the years 1986-2010. TC 4.2 also produced a new ASHRAE clear-sky model (RP-1453) that is applicable worldwide-a significant improvement over the old model, which was only valid for the continental United States. TC 4.2 has also developed improved methods (RP-1363) for generating design day temperature profiles.
- TC 4.4, Building Materials and Building Envelope Performance, has provided a major revision of the building thermal properties data.

In addition to acknowledging the members of the above technical committees and their contractors, I would also like to thank the members of the Project Monitoring Subcommittee who have overseen this work: Steve Bruning, Jim Pegues, Bob Doeffinger, Larry Sun, and Chris Wilkins. Their oversight and suggestions have been invaluable.

I have been assisted on this project by three students at Oklahoma State University: a graduate student, Laura Southard, and two undergraduate students, Jimmy Kim and Amy Wong, who have helped with developing revised examples and source code for the changes to the accompanying spreadsheets.

Putting together this book from a set of the author's Word files was a big task requiring quite a bit of attention to detail. I greatly appreciate the work of the ASHRAE staff, especially Sarah Boyle, assistant editor of Special Publications, in editing and typesetting the book. Cindy Michaels, Managing editor of Special Publications, was also very helpful in getting me access to handbook chapters as soon as they became available. Thanks to both of you!

I would like to take the author's prerogative to note three longtime ASHRAE TC 4.1 members who passed away during 2011 and 2012. Lynn G. Bellenger was not only an active TC 4.1 member, but very active in all areas of ASHRAE, serving as the first female ASHRAE President in 2010 and 2011. Lynn was an encouragement to many society members.

Two other TC 4.1 stalwarts, Thomas B. Romine, Jr. and Curtis O. Pedersen, both passed away in July of 2012. Tom was a consulting engineer in Fort Worth, Texas who ably represented the viewpoint of the consulting engineer on the technical committee and helped me keep the end user in mind when I was working on some of the earlier load calculation manuals. Curt was a professor at the University of Illinois at

## Load Calculation Applications Manual (I-P), Second Edition

Urbana-Champaign, my PhD advisor, an investigator on several load calculationrelated research projects, and proponent of using fundamental methods-i.e., the heat balance method-for load calculations. Both men have had a great impact on the load calculation methodologies presented in this book.

Jeffrey D. Spitler, PhD, PE

Introduction

This manual focuses on two methods for calculating cooling loads in nonresidential buildings-the heat balance method (HBM) and the radiant time series method (RTSM). The two methods presented are based on fundamental heat balance principles, directly so in the case of the HBM, and less directly so in the case of the RTSM. Both methods were first fully presented for use in design load calculations in the predecessor to this volume, Cooling and Heating Load Calculation Principles (Pedersen et al. 1998). Since that time, there have been a number of developments in the RTSM. This publication attempts to bring the previous volume up to date, incorporate new developments, and provide a more in-depth treatment of the method. This edition incorporates recent improvements in available data for weather, building materials, fenestration, and internal heat gains and improved methods for predicting clear-sky radiation, design day temperatures, and solar heat gains from fenestration.

This publication is accompanied by a set of spreadsheets and a set of weather files, which can be found at ashrae.org/lcam. The spreadsheets support the more complex examples in the book; the weather files provided the needed weather information to perform load calculations around the world. If the files or information at the link are not accessible, please contact the publisher.

### 1.1 Definition of a Cooling Load

When an HVAC system is operating, the rate at which it removes heat from a space is the instantaneous heat extraction rate for that space. The concept of a design cooling load derives from the need to determine an HVAC system size that, under extreme conditions, will provide some specified condition within a space. The space served by an HVAC system commonly is referred to as a thermal zone or just a zone. Usually, the indoor boundary condition associated with a cooling load calculation is a constant interior dry-bulb temperature, but it could be a more complex function, such as a thermal comfort condition. What constitutes extreme conditions can be interpreted in many ways. Generally, for an office it would be assumed to be a clear sunlit day with high outdoor wet-bulb and dry-bulb temperatures, high office occupancy, and a correspondingly high use of equipment and lights. Design conditions assumed for a cooling load determination are subjective. However, after the design conditions are agreed upon, the design cooling load represents the maximumor peak heat extraction-rate under those conditions.

### 1.2 The Basic Design Questions

In considering the problem of design from the HVAC system engineer's viewpoint, a designer needs to address the following three main questions:

1. What is the required equipment size?
2. How do the heating/cooling requirements vary spatially within the building?
3. What are the relative sizes of the various contributors to the heating/cooling load?

The cooling load calculation is performed primarily to answer the second question, that is, to provide a basis for specifying the required airflow to individual spaces within the

AIR CONDITIONING COMPANY

## Load Calculation Applications Manual (SI), Second Edition

building. The calculation also is critical to professionally answering the first question. Answers to the third question help the designer make choices to improve the performance or efficiency of the design and occasionally may influence architectural designers regarding energy-sensitive consequences.

### 1.3 Overview of the ASHRAE Load Calculation Methods

### 1.3.1 Models and Reality

All calculation procedures involve some kind of model, and all models are approximate. The amount of detail involved in a model depends on the purpose of that model. This is the reality of modeling, which should describe only the variables and parameters that are significant to the problem at hand. The challenge is to ensure that no significant aspects of the process or device being modeled are excluded and, at the same time, that unnecessary detail is avoided.

A complete, detailed model of all of the heat transfer processes occurring in a building would be very complex and would be impractical as a computational model, even today. However, building physics researchers and practitioners generally agree that certain modeling simplifications are reasonable and appropriate under a broad range of situations. The most fundamental of these is that the air in the space can be modeled as well-stirred. This means there is an approximately uniform temperature throughout the space due to mixing. This modeling assumption is quite valid over a wide range of conditions. With that as a basis, it is possible to formulate fundamental models for the various heat transfer and thermodynamic processes that occur. The resulting formulation is called the HBM. There is an introduction to the general principles of the HBM in Chapter 2 and further description in Chapter 11.

### 1.3.2 The Heat Balance Method

The processes that make up the heat balance model can be visualized using the schematic shown in Figure 1.1. It consists of four distinct processes:

1. Outside face heat balance
2. Wall conduction process
3. Inside face heat balance
4. Air heat balance

Figure 1.1 shows the heat balance process in detail for a single opaque surface. The shaded part of the figure is replicated for each of the surfaces enclosing the zone.

The process for transparent surfaces is similar to that shown but does not have the absorbed solar component at the outside surface. Instead, it is split into two parts: an inward-flowing fraction and an outward-flowing fraction. These fractional parts participate in the inside and outside face heat balances. The transparent surfaces, of course, provide the transmitted solar component that contributes to the inside heat balance.

The double-ended arrows indicate schematically where there is a heat exchange, and the single-ended arrows indicate where the interaction is one way. The formulation of the heat balance consists of mathematically describing the four major processes, shown as rounded blocks in the figure.

### 1.3.3 The Radiant Time Series Method

The RTSM is a relatively new method for performing design cooling load calculations. It is derived directly from the HBM and effectively replaced all other simplified (non-heat-balance) methods such as the transfer function method (TFM), the cooling

AIR CONDITIONING COMPANY

Figure 1.1 Schematic of heat balance process in a zone.
(Source: Cooling and Heating Load Calculation Principles, Figure 1.1).
load temperature difference/solar cooling load/cooling load factor method (CLTD/SCL/ CLFM), and the total equivalent temperature difference/time averaging method (TETD/ TAM). The RTSM was developed in response to a desire to offer a method that was rigorous yet did not require the iterative calculations of the previous methods. In addition, the periodic response factors and radiant time factors have clear physical meanings; when plotted, they allow the user to visually see the effects of damping and time delay on conduction heat gains and zone response.

The utility of the RTSM lies in the clarity, not the simplicity, of the procedure. Although the RTSM uses a "reduced" heat balance procedure to generate the radiant time series (RTS) coefficients, it is approximately as computationally intensive as the heat balance procedure upon which it is based. What the RTS method does offer is insight into the building physics without the computational rigor of the HBM, a sacrifice in accuracy that is surprisingly small in most cases. Previous simplified methods relied on room transfer function coefficients that completely obscured the actual heat transfer processes they modeled. The heat-balance-based RTS coefficients, on the other hand, provide some insight into the relationship between zone construction and the time dependence of the building heat transfer processes. The RTSM abstracts the building thermal response from the fundamentally rigorous heat balance and presents the effects of complex, interdependent physical processes in terms that are relatively easy to understand. The abstraction requires a number of simplifying assumptions and approximations. These are covered in Section 7.1. Figure 1.2 shows the computational procedure that defines the RTSM. A more detailed schematic is shown in Chapter 7.

In the RTSM, a conductive heat gain for each surface is first calculated using air-toair response factors. The conductive heat gains and the internal heat gains are then split into radiant and convective portions. All convective portions are instantaneously converted to cooling loads and summed to obtain the fraction of the total hourly cooling load caused by convection.

## Load Calculation Applications Manual (SI), Second Edition

Figure 1.2 Schematic of the radiant time series method.
(Source: Cooling and Heating Load Calculation Principles, Figure 1.2).

Radiant heat gains from conduction, internal sources, and solar transmission are operated on by the RTS to determine the fraction of the heat gain that will be converted to a cooling load in current and subsequent hours. These fractional cooling loads are added to the previously calculated convective portions at the appropriate hour to obtain the total hourly cooling load.

### 1.4 Organization of the Manual

This manual is organized to roughly proceed from the general to the specific. Chapter 2 provides an overview of the heat transfer processes present in buildings and a brief discussion of how they are analyzed together in order to determine the building cooling load. Chapters 3-6 cover thermal properties, design conditions, infiltration, and internal heat gains-all of which are relevant to all load calculation methods. Chapters 7 and 8 cover the theory and application of the RTSM. Chapter 9 covers systems and psychrometrics, analyses of which are necessary to determine equipment sizes. Chapter 10 considers heating load calculations. Chapter 11 covers the HBM and its implementation.

Throughout the manual, numerous shaded examples are presented to illustrate various aspects of the RTSM. A number of the examples are performed using spreadsheets that are included in the supporting files online at www.ashrae.org/lcam.

## References

## Fundamentals of Heat Transfer and Thermodynamics

T
he cooling load is defined as the amount of heat that must be removed from the room air to maintain a constant room air temperature. Conversely, the heating load is the amount of heat that must be added to the room air. To determine these quantities, it is necessary to estimate the heat transmission into or out of the room. In turn, this requires analysis of all three modes of heat transfer-conduction, convection, and radiation- within the building envelope and between the building envelope and its surroundings. (Here, the term building envelope refers to the walls, roofs, floors, and fenestrations that make up the building.)

The three modes of heat transfer all occur simultaneously, and it is the simultaneous solution of all three modes of heat transfer that complicates the analysis. In practice, this simultaneous solution is done with a computer program either during the load calculation procedure (e.g., the heat balance method [HBM]) or prior to the load calculation procedure (all simplified load calculation procedures rely on tabulated factors that were developed with a simultaneous solution of all three modes of heat transfer).

Before concerning ourselves with the simultaneous solution, we should first consider the three modes independently. For convection and radiation, the treatment of the individual modes of heat transfer does not go far beyond what is taught in a first undergraduate course ${ }^{1}$ in heat transfer. For steady-state conduction heat transfer, as used in heating load calculations, this is also the case. For transient conduction heat transfer, as used in cooling load calculations, the derivation of the solution procedure can be somewhat complex, although its application, in practice, is not very difficult.

Each of the three modes is discussed briefly below. Then, after considering the three modes of heat transfer, the simultaneous solution-based on the first law of thermodynamics-is briefly discussed.

### 2.1 Conduction-Steady State

Heat transfer through building walls and roofs is generally treated as a pure conduction heat transfer process, even though, for example, convection and radiation may be important in an internal air gap ${ }^{2}$ in the wall. Conduction is the transfer of heat through a solid ${ }^{3}$ via random atomic and molecular motion in response to a temperature gradient. Elements of the building envelope such as thermal bridges and corners distort the temperature gradients so that the heat flows in directions other than purely perpendicular to the envelope surfaces. Such heat flow is said to be multidimensional. For building load calculations, multidimensional conduction heat transfer is generally approximated as being one-dimensional; however, the approximations do take into account the impact of thermal bridges. ${ }^{4}$ Heat loss from foundation elements is also multidimensional, but again, approximations are made that simplify the calculation procedure.

[^0]AIR CONDITIONING COMPANY

One-dimensional steady-state heat conduction is described by the Fourier equation:

$$
\begin{equation*}
\dot{q}=-k A \frac{d t}{d x} \tag{2.1}
\end{equation*}
$$

where
$\dot{q}=$ heat transfer rate, W
$k=$ thermal conductivity, $\mathrm{W} /(\mathrm{m} \cdot \mathrm{K})$
$A=$ area normal to the heat flow, $\mathrm{m}^{2}$
$\frac{d t}{d x}=$ temperature gradient, ${ }^{\circ} \mathrm{C} / \mathrm{m}$
For a single layer of a wall with heat flow in the $x$ direction and with conductivity $k$ and surface temperatures $t_{2}$ and $t_{1}$, as shown in Figure 2.1, Equation 2.1 can be integrated to give

$$
\begin{equation*}
\dot{q}=-k A \frac{\left(t_{2}-t_{1}\right)}{\left(x_{2}-x_{1}\right)} \tag{2.2}
\end{equation*}
$$

A convenient form of Equation 2.2 involves the definition of the unit thermal resistance $R$ :

$$
\begin{equation*}
R=\frac{\left(x_{2}-x_{1}\right)}{k}=\frac{\Delta x}{k} \tag{2.3}
\end{equation*}
$$

where
$R=$ unit thermal resistance, $\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right) / \mathrm{W}$
$\Delta x=$ thickness of the layer, units are consistent with $k, \mathrm{~mm}$
Then, the conduction heat transfer rate through the wall is given by

$$
\begin{equation*}
\dot{q}=A \frac{\left(t_{1}-t_{2}\right)}{R} \tag{2.4}
\end{equation*}
$$

Figure 2.1 A single-layer plane wall.

Example 2.1 Wall Heat Loss

A 0.1 m thick uninsulated wall with an area of $10 \mathrm{~m}^{2}$ is made out of concrete with a conductivity of $1.15 \mathrm{~W} /(\mathrm{m} \cdot \mathrm{K})$. What is the R-value of the wall? Under steady-state conditions, with the exterior surface temperature of the wall at $0^{\circ} \mathrm{C}$ and the interior surface temperature of the wall at $15^{\circ} \mathrm{C}$, what is the total heat loss through the wall?

Solution: The R-value is determined by dividing the thickness by the conductivity:

$$
R=0.1 \mathrm{~m} / 1.15 \mathrm{~W} /(\mathrm{m} \cdot \mathrm{~K})=0.09\left(\mathrm{~m}^{2} \cdot \mathrm{~K}\right) / \mathrm{W}
$$

The conduction heat transfer rate through the wall is given by Equation 2.4:

$$
\dot{q}=10 \mathrm{~m}^{2} \frac{\left(15^{\circ} \mathrm{C}-0^{\circ} \mathrm{C}\right)}{0.09 \frac{\mathrm{~m}^{2} \cdot \mathrm{~K}}{\mathrm{~W}}}=1667 \mathrm{~W}
$$

A more common situation is that the wall has multiple layers, as shown in Figure 2.2. Here, the wall is made up of three layers with two exterior surfaces (one and four) and two interior interfaces (two and three). Each of the three layers is defined by a conductivity (e.g., $k_{2-1}$ for the leftmost layer) and thickness (e.g., $\Delta x_{2-1}$ for the leftmost layer).

Individual unit thermal resistances are determined for each layer:

$$
\begin{align*}
& R_{2-1}=\frac{\Delta x_{2-1}}{k_{2-1}}  \tag{2.5a}\\
& R_{3-2}=\frac{\Delta x_{3-2}}{k_{3-2}}  \tag{2.5b}\\
& R_{4-3}=\frac{\Delta x_{4-3}}{k_{4-3}} \tag{2.5c}
\end{align*}
$$

Figure 2.2 A multilayer wall.

Figure 2.3 Multilayer wall analysis based on electrical analogy.

There is an analogy between conduction heat transfer and electricity, as illustrated in Figure 2.3, where the unit thermal resistances (analogous to electrical resistances ${ }^{5}$ per unit area) are shown connecting the surface temperatures (analogous to voltages). As a consequence, the total unit thermal resistance of the wall may be determined by simply adding the three individual unit thermal resistances (in series):

$$
\begin{equation*}
R_{4-1}=R_{2-1}+R_{3-2}+R_{4-3} \tag{2.6}
\end{equation*}
$$

Then, the heat flux (analogous to current per unit area) may be determined as

$$
\begin{equation*}
q^{\prime \prime}=\frac{\left(t_{1}-t_{4}\right)}{R} \tag{2.7}
\end{equation*}
$$

where
$\mathrm{q}^{\prime \prime}=$ heat flux rate (heat transfer rate per unit area), $\mathrm{W} / \mathrm{m}^{2}$

## Example 2.2 <br> Series <br> Resistances

The concrete wall of Example 2.1 is improved by adding a 0.05 m thick layer of expanded polystyrene, with an R-value of 1.76 , and a layer of 0.013 m thick drywall, with an R -value of 0.08 . With these additional layers, what is the R -value of the wall? Under steady-state conditions, with the exterior surface temperature of the wall at $0^{\circ} \mathrm{C}$ and the interior surface temperature of the wall at $15^{\circ} \mathrm{C}$, what is the total heat loss through the wall?

Solution: Because the three layers are in a series with each other, the total Rvalue is determined by adding the resistances of the three layers, as modeled in Equation 2.6:
5. The analogy is to discrete electrical resistors when expressed in thermal resistances $\left(R^{\prime}=\Delta x / k A\right)$ and heat transfer rates. For one-dimensional planar walls, it is often convenient to consider the analogy on a per-unit-area basis, in which case it may be expressed in terms of unit thermal resistances and heat fluxes (heat transfer rates per unit area).

AIR CONDITIONING COMPANY

## Fundamentals of Heat Transfer and Thermodynamics

$$
R=0.09+1.76+0.08=1.93\left(\mathrm{~m}^{2} \cdot \mathrm{~K}\right) / \mathrm{W}
$$

The conduction heat transfer rate through the wall is given by Equation 2.4:

$$
\dot{q}=10 \mathrm{~m}^{2} \frac{\left(15^{\circ} \mathrm{C}-0^{\circ} \mathrm{C}\right)}{1.93 \frac{\mathrm{~m}^{2} \cdot \mathrm{~K}}{\mathrm{~W}}}=78 \mathrm{~W}
$$

A dramatic reduction in heat loss can generally be had when insulation is added to uninsulated walls.

Generally, heating load calculations are performed for conditions that are assumed to be approximately steady-state: that is, evening hours after the building occupants have gone home and the sun has gone down. In this case, the conduction heat transfer through the above-grade portion of the building envelope is determined by first calculating the overall thermal resistance and conductance (U-factor) of each surface, multiplying the U-factors by the surface areas, summing the UA (U-factor • area) values for each room, and multiplying the total UA for each room by the design temperature difference. For slab-on-grade floors, basement walls, and basement floors, a simple multidimensional analysis is used such that the solution is given in one-dimensional form.

### 2.2 Thermal Storage and Transient Conduction

The discussion of conduction heat transfer in Section 2.1 treated it as a steadystate phenomenon. While for heating load calculations this is generally sufficient, strong daily variations in incident solar radiation and outdoor air temperatures occurring under cooling load design conditions cannot be ignored in most cases. This is particularly true as the thermal capacitance of the wall or roof increases. Thermal capacitance of a wall or roof element may be defined as the amount of energy required to raise the temperature by one degree:

$$
\begin{equation*}
C_{t h}=M C_{p}=\rho V C_{p} \tag{2.8}
\end{equation*}
$$

where
$C_{t h}=$ thermal capacitance of a wall or roof layer, $\mathrm{kJ} / \mathrm{K}$
$M=$ mass of the wall or roof layer, kg
$C_{p}=$ specific heat of the wall or roof layer material, $\mathrm{kJ} /(\mathrm{kg} \cdot \mathrm{K})$
$\rho=$ density of the wall or roof layer material, $\mathrm{kg} / \mathrm{m}^{3}$
$V=$ volume of the wall or roof layer, $\mathrm{m}^{3}$

The energy required to raise the temperature of the layer is then given by

$$
\begin{equation*}
Q=C_{t h} \Delta T=M C_{p} \Delta T=\rho V C_{p} \Delta T \tag{2.9}
\end{equation*}
$$

where
$\Delta T=$ temperature increase, K

Example 2.3 Thermal Storage

Consider the 0.1 m thick layer of concrete in the $10 \mathrm{~m}^{2}$ wall in Example 2.2. During a design cooling day, it is warmed from a temperature of $21^{\circ} \mathrm{C}$ to a temperature of $27^{\circ} \mathrm{C}$. If the concrete has a density of $2240 \mathrm{~kg} / \mathrm{m}^{3}$ and a specific heat of $0.92 \mathrm{~kJ} /(\mathrm{kg} \cdot \mathrm{K})$, how much energy is absorbed in warming the concrete layer?

Solution: The total volume of the concrete is $1 \mathrm{~m}^{3}$; multiplying by the density gives the total mass of the concrete as 2240 kg . The required energy input is the mass multiplied by the specific heat multiplied by the rise in temperature:

$$
Q=2240 \mathrm{~kg} \cdot 0.92 \mathrm{~kJ} /(\mathrm{kg} \cdot \mathrm{~K}) \cdot 6^{\circ} \mathrm{C}=12,365 \mathrm{~kJ}
$$

Comparing the amount of energy required to raise the temperature of the layer by $6^{\circ} \mathrm{C}$ to the expected heat transmission rate under steady-state conditions suggests that this heat storage effect will not be unimportant. However, because the thermal capacitance is distributed throughout each layer, there is no simple way to calculate the transient behavior. The distributed thermal capacitance is sometimes represented as shown in Figure 2.4, with the two parallel lines below each resistance representing the distributed capacitance.

While a range of solution procedures (Spitler 1996) are possible (e.g., finite difference methods, finite volume methods, lumped parameter methods, frequency response methods, etc.), ASHRAE design cooling load calculations use either conduction transfer functions (CTFs) in the heat balance method or a form of periodic response factors, known as the conduction time series factors (CTSFs) in the radiant time series method (RTSM). The two methods are covered in Chapters 11 and 7, respectively. Software for calculating CTFs and CTSFs is included on the accompanying supporting files (online at www.ashrae.org/lcam) and is described in Appendix C.

To further illustrate the effects of thermal storage in the wall, consider what would happen if the three-layer ( 10 cm concrete, $\mathrm{R}-1.76$ insulation, 1.3 cm drywall) wall described in Example 2.2 was placed in an office building in Atlanta, facing southwest. Under cooling load design conditions, the heat transmission through the wall may be calculated using two methods:

- A method that ignores the thermal mass in the wall, computing the conduction heat gain with Equation 2.4 at each hour of the day. In this case, the exterior temperature changing throughout the day gives conduction heat gains that change over the day. This method may be referred to as quasi-steady-state because it treats each hour of the day as if the wall comes immediately to steady-state conditions. (Labeled Quasi-SS in Figure 2.5.)
- The method described in Chapter 7, which takes into account the thermal capacitance of each layer. (Labeled Transient in Figure 2.5.)

Conduction heat gains computed with each method are shown in Figure 2.5. In this figure, two effects of the thermal mass may be observed:

- The first may be referred to as time delay-the peak heat gain, when calculated with the quasi-steady-state method, appears to occur at 5:00 p.m. When the thermal capacitance is accounted for in the calculation, we can see that the peak heat gain actually occurs at 9:00 p.m. This four-hour delay in the peak heat gain may be important, especially if the peak heat gain is delayed such that it occurs after the occupants have gone home.
- The second effect may be referred to as damping-the peak heat gain, when calcu-
lated with the transient method, is about $30 \%$ lower than that calculated with the quasi-steady-state method.

Both effects are important, and this is why transient conduction calculations are typically performed as part of the cooling load calculation procedure.

### 2.3 Convection

Thermal convection is the transport of energy in a fluid or gas by mixing in addition to conduction. For load calculations, we are primarily interested in convection between an envelope surface (e.g., wall, roof) and the indoor or outdoor air. The rate of convection heat transfer depends on the temperature difference, whether the flow is laminar or turbulent, and whether it is buoyancy driven or driven by an external flow. The convection heat transfer rate is usually expressed ${ }^{6}$ as

$$
\begin{equation*}
\dot{q}=h A\left(t-t_{s}\right) \tag{2.10}
\end{equation*}
$$

where
$h=$ convection coefficient, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
$t=$ bulk temperature of the air, ${ }^{\circ} \mathrm{C}$
$t_{s}=$ surface temperature, ${ }^{\circ} \mathrm{C}$
The convection coefficient, often referred to as the film coefficient, may be estimated with a convection correlation or, for design conditions, may be read from a table.

## Example 2.4 <br> Convection

A wall with a surface area of $10 \mathrm{~m}^{2}$ is heated by the sun to a temperature of $60^{\circ} \mathrm{C}$ at a time when the outdoor air is at $21^{\circ} \mathrm{C}$, and a light breeze results in a convection coefficient of $28 \mathrm{~W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$. What is the heat lost by the surface due to convection?

Solution: Equation 2.10 gives the heat transferred to the surface by convection. The heat transferred away from the surface by convection would be given by

$$
\dot{q}=h A\left(t_{s}-t\right)=28 \frac{\mathrm{~W}}{\mathrm{~m}^{2} \cdot \mathrm{~K}}\left(10 \mathrm{~m}^{2}\right)\left(60^{\circ} \mathrm{C}-21^{\circ} \mathrm{C}\right)=10,920 \mathrm{~W}
$$

### 2.4 Radiation-Long Wave and Short Wave

Thermal radiation is the transfer of energy by electromagnetic waves. In building load calculations, thermal radiation is generally thought of as being a surface-to-surface phenomenon either between surfaces within the building or between the surface of the sun and the building surfaces. Gases, aerosols, and particulates also emit and absorb radiation between surfaces. However, for analysis of radiation heat transfer between surfaces within a building, the path lengths are short enough that emission and absorption of the indoor air can be neglected. For radiation heat transfer between the sun and the building surfaces, emission and
6. Also known as Newton's Law of Cooling.

Figure 2.5 Comparison of transient and quasi-steady-state conduction heat gain calculations.
absorption in the earth's atmosphere is accounted for in the models used to determine incident solar irradiation.

Thermal radiation emitted by any surface will have a range of wavelengths, depending upon the temperature of the emitting surface. The amount of thermal radiation absorbed, reflected, or emitted by any surface will depend on the wavelengths and direction in which the radiation is incident or emitted relative to the surface. Dependency on the wavelength is referred to as spectral; surfaces for which the properties are effectively independent of the wavelength are referred to as gray surfaces. Dependency on the direction is referred to as specular; surfaces for which the properties are effectively independent of the direction are referred to as diffuse surfaces. Properties of interest include the following:

- Absorptance, ${ }^{7} \alpha$, the ratio of radiation absorbed by a surface to that incident on the

Figure 2.4 Electrical analogy with distributed thermal capacitance.
surface

- Emittance, $\varepsilon$, the ratio of radiation emitted by a surface to that emitted by an ideal "black" surface at the same temperature
- Reflectance, $\rho$, the ratio of radiation reflected by a surface to that incident on the surface
- Transmittance, $\tau$, the ratio of radiation transmitted by a translucent surface to that incident on the surface

Analysis of thermal radiation is greatly simplified when the surfaces may be treated as gray and diffuse. With two exceptions, surfaces in buildings are treated as both gray and diffuse in load calculation procedures.

The first exception is based on the fact that thermal radiation wavelength distributions prevalent in buildings may be approximately lumped into two catego-ries- short-wavelength radiation (solar radiation or visible radiation emitted by lighting) and long-wavelength radiation (radiation emitted by surfaces, people, equipment, etc. that is all at relatively low temperatures compared to the sun). Treatment of the two wavelength distributions separately in building load calculations might be referred to as a two-band model, but in practice this only means that surfaces may have different absorptances for short-wavelength radiation and long-wavelength radiation. As an example, consider that a surface painted white may have a short-wavelength absorptance of 0.4 and a long-wavelength absorptance of 0.9 .

The second exception is for analysis of windows. Solar radiation is typically divided into specular (direct or beam) and diffuse components as described in Appendix D. Because the window absorptance, reflectance, and transmittance tend to be moderately strong functions of the incidence angle, these properties are generally calculated for the specific incidence angle each hour.

A notable feature of thermal radiation is that the emission is proportional to the fourth power of the absolute temperature (i.e., degrees Rankine or Kelvin.) As an example, consider a case with only two surfaces separated by a nonparticipating medium. The radiation heat transfer rate between surfaces 1 and 2 is given by

$$
\begin{equation*}
\dot{q}_{1-2}=\frac{\sigma\left(T_{1}^{4}-T_{2}^{4}\right)}{\frac{1-\varepsilon_{1}}{A_{1} \varepsilon_{1}}+\frac{1}{A_{1} F_{1-2}}+\frac{1-\varepsilon_{2}}{A_{2} \varepsilon_{2}}} \tag{2.11}
\end{equation*}
$$

where
$\sigma \quad=$ Stefan-Boltzmann constant, $5.67 \cdot 10^{-8} \mathrm{~W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}^{4}\right)$
$T_{1}$ and $T_{2}=$ surface temperatures of surfaces 1 and $2, \mathrm{~K}$
$\varepsilon_{1}$ and $\varepsilon_{2}=$ emittances of surfaces 1 and 2
$F_{1-2} \quad=$ view factor from surface 1 to surface 2
In practice, rooms in buildings have more than two surfaces and, in general, every surface exchanges radiation heat transfer with every other surface. While it is possible
7. Despite some attempts to reserve the endings "-ivity" for optically pure surfaces and "-tance" for realworld surfaces, the terms absorptivity, emissivity, reflectivity, and transmissivity are often used interchangeably for absorptance, emittance, reflectance, and transmittance.

## Example 2.5 Radiation

A $10 \mathrm{~m}^{2}$ wall has an air gap separating a layer of brick and a layer of concrete block. At a time when the temperature of the brick surface adjacent to the air gap is $-1.1^{\circ} \mathrm{C}$ and the temperature of the concrete block surface adjacent to the air gap is $7.2^{\circ} \mathrm{C}$, what is the radiation heat transfer rate across the air gap?

Solution: The radiation heat transfer rate can be calculated with Equation 2.11. To use Equation 2.11, there are a few terms that must first be evaluated. First, the temperatures $T_{1}$ and $T_{2}$ are needed in absolute temperature or degrees Kelvin. Taking the concrete block as surface 1 and the brick as surface 2,

$$
\begin{aligned}
& T_{1}=t_{1}+273.15=72+273.15=280.35 \mathrm{~K} \\
& T_{2}=t_{2}+273.15=-1.1+273.15=272.05 \mathrm{~K}
\end{aligned}
$$

The surface emissivities are not given, but, in general, for building materials that are not polished metals, a value of 0.9 is a reasonable assumption.

The view factor between two parallel surfaces facing each other is approximately one. Equation 2.9 can then be evaluated as

$$
\dot{q}_{1-2}=\frac{\sigma\left(280.35^{4}-272.05^{4}\right)}{\frac{1-0.9}{10 \cdot 0.9}+\frac{1}{10 \cdot 1}+\frac{1-0.9}{10 \cdot 0.9}}=325 \mathrm{~W}
$$

If a low emissivity coating (e.g., a layer of aluminum foil) were applied to the concrete block layer and not compromised by being splattered with mortar or coated with dust during the bricklaying, the emittance might be as low as 0.05 . (In practice, this would be nearly impossible, but just for purposes of example, we'll assume that it might be done.) The radiation heat transfer could then be calculated as

$$
\dot{q}_{1-2}=\frac{\sigma\left(280.35^{4}-272.05^{4}\right)}{\frac{1-0.05}{10 \cdot 0.05}+\frac{1}{10 \cdot 1}+\frac{1-0.9}{10 \cdot 0.9}}=20 \mathrm{~W}
$$

to analyze the complete radiation network, load calculations typically adopt a simpler approximation. For the HBM, a mean radiant temperature approach, as described in Chapter 11, is usually adopted. For the RTSM, the analysis of the radiation heat transfer to/from inside and outside surfaces is combined with the analysis of convection, as described in the next section.

### 2.5 Combined Convection and Radiation

An important feature of simplified load calculation methods, like the RTSM, is that convection and radiation analysis are often combined into a single surface conductance. This requires a linear approximation of the radiation heat transfer. Considering that surface 2 in Equation 2.11 above could represent, in aggregate, the surroundings, then approximately $A_{2}$ » $A_{1}$ and Equation 2.11 can be simplified to

$$
\begin{equation*}
\dot{q}_{1-2}=A_{1} \varepsilon_{1} \sigma\left(T_{1}^{4}-T_{2}^{4}\right)=A_{1} h_{r}\left(T_{1}-T_{2}\right) \tag{2.12}
\end{equation*}
$$

$$
\begin{equation*}
h_{r}=\varepsilon_{1} \sigma\left(T_{1}^{2}+T_{2}^{2}\right)\left(T_{1}+T_{2}\right) \approx 4 \varepsilon_{1} \sigma \bar{T}^{3} \tag{2.13}
\end{equation*}
$$

where
$h_{r}=$ radiation coefficient, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
$T=$ mean temperature, K
Note that while the linearized radiation coefficient is calculated with absolute temperatures, it is applied to a temperature difference, so it may just as easily be used to predict radiation heat transfer with the difference in, say, degrees Fahrenheit:

$$
\begin{equation*}
\dot{q}_{r}=h_{r} A\left(t-t_{w}\right) \tag{2.14}
\end{equation*}
$$

The surface conductance, which combines the radiation and convection coefficient, can then be defined as

$$
\begin{equation*}
h_{o}=h_{c}+h_{r} \tag{2.15}
\end{equation*}
$$

This has the advantage of allowing the combined convection and radiation heat transfer rate to be expressed as

$$
\begin{equation*}
\dot{q}=h_{o} A\left(t-t_{w}\right) \tag{2.16}
\end{equation*}
$$

Or, the inverse of the surface conductance can be treated as a conductive resistance, simplifying the analysis so that it appears as simply a conduction analysis. Though the surface conductance depends on both the value of the convection coefficient and the surface and surroundings temperatures, standard values for design purposes are tabulated in Chapter 3.

In the case of the exterior conductance, the problem is further complicated by the presence of solar radiation. For simplified load calculation procedures, an equivalent air temperature, or the sol-air temperature, is defined that gives approximately the same heat flux to the surface as the combined effects of solar radiation, convection, and radiation to the surroundings. It is given by

$$
\begin{equation*}
t_{e}=t_{o}+\alpha G_{t} / h_{o}-\varepsilon \delta R / h_{o} \tag{2.17}
\end{equation*}
$$

where
$t_{e}=$ sol-air temperature, ${ }^{\circ} \mathrm{C}$
$t_{o}=$ outdoor air temperature, ${ }^{\circ} \mathrm{C}$
$\alpha=$ absorptance of the surface to solar radiation
$G_{t}=$ total incident solar radiation flux, W• $\mathrm{m}^{2}$
$h_{o}=$ exterior surface conductance, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
$\varepsilon \quad=$ exterior surface emittance
$\delta R=$ difference between the thermal radiation incident on the surface from the sky or surroundings and the radiation emitted by a blackbody at the outdoor air temperature, $\mathrm{W} \cdot \mathrm{m}^{2}$

The last term, $\varepsilon \delta R / h_{o}$, is typically taken as $4^{\circ} \mathrm{C}$ for horizontal surfaces (i.e., facing the sky) and $0^{\circ} \mathrm{C}$ for vertical surfaces.

## azarnasimb

For the interior conductance, the indoor air temperature is taken as a suitable approximation to the actual effective temperature with which convection and radiation are exchanged.

The use of linearized radiation coefficients, combined with convection coefficients into surface conductances, allows the heat gains from each wall to be added without considering interaction between the surfaces or the possibility that heat may be conducted out under some circumstances by windows or other high-conductance surfaces. These effects are usually small but may be corrected for with the procedure described in Appendix G. In order to account for these effects more accurately, it is necessary to apply the HBM, which is introduced in the next section and more fully described in Chapter 11.

### 2.6 The First Law of Thermodynamics-Heat Balance

The HBM takes its name from the application of the first law of thermodynam-ics-energy is conserved-to the inner and outer surfaces of the building envelope and the zone air. All of the energy involved is in the form of heat, hence the term heat balance.

As an example, consider the exterior surface of a wall, as shown in Figure 2.6, where
$t_{e s} \quad=$ exterior surface temperature, ${ }^{\circ} \mathrm{C}$
$t_{i s} \quad=$ interior surface temperature, ${ }^{\circ} \mathrm{C}$
$t_{o} \quad=$ outdoor air temperature, ${ }^{\circ} \mathrm{C}$
$q_{\text {solar }}^{\prime \prime}=$ absorbed solar heat flux, $\mathrm{W} / \mathrm{m}^{2}$
$t_{\text {surr }}=$ temperature of the surroundings, ${ }^{\circ} \mathrm{C}$
Neglecting any transient effects, a heat balance on the exterior surface might be written as

$$
\begin{equation*}
q_{\text {conduction }}^{\prime \prime}=q_{\text {solar }}^{\prime \prime}+q_{\text {convection }}^{\prime \prime}+q_{\text {radiation }}^{\prime \prime} \tag{2.18}
\end{equation*}
$$

with each component of the heat transfer defined as follows:

$$
\begin{equation*}
q_{\text {conduction }}^{\prime \prime}=U_{s-s}\left(t_{e s}-t_{i s}\right) \tag{2.19}
\end{equation*}
$$

Figure 2.6 Exterior surface heat balance.

$$
\begin{gather*}
q_{\text {solar }}^{\prime \prime}=\alpha G_{t}  \tag{2.20}\\
q_{\text {convection }}^{\prime \prime}=h_{c}\left(t_{o}-t_{e s}\right)  \tag{2.21}\\
q_{\text {radiation }}^{\prime \prime}=h_{r}\left(t_{\text {surr }}-t_{e s}\right) \tag{2.22}
\end{gather*}
$$

where
$U_{s-s}=$ surface-to-surface conductance, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
$\alpha \quad=$ absorptance of the surface to solar radiation
$G_{t}=$ total incident solar radiation flux, $\mathrm{W} / \mathrm{m}^{2}$
$h_{c} \quad=$ exterior surface convection coefficient, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
$h_{r} \quad=$ exterior surface radiation coefficient, $\mathrm{W} /\left(\mathrm{m}^{2} \cdot \mathrm{~K}\right)$
Here, the radiation heat transfer has been linearized, though in the heat balance solution procedure, the radiation heat transfer coefficient will be recalculated on an iterative basis. Substituting Equations 2.19-2.22 into Equation 2.18, the exterior surface temperature can then be determined:

$$
\begin{equation*}
t_{e s}=\frac{\alpha G_{t}+U_{s-s} t_{i s}+h_{c} t_{o}+h_{r} t_{s u r r}}{U_{s-s}+h_{c}+h_{r}} \tag{2.23}
\end{equation*}
$$

A similar procedure for the interior surface yields a similar equation for the interior surface temperature. The interior and exterior surface temperatures would then be solved iteratively. When all interior surface temperatures are known, the cooling load can be calculated as the sum of the convective heat gains from the interior surfaces, lighting, equipment, people, and infiltration.

In practice, these calculations are further complicated by the transient conduction heat transfer and the need to analyze all modes of heat transfer simultaneously for all surfaces in a room. For more information, see Chapter 11.

## Thermal Property Data

Analysis of walls and roofs for cooling or heating load calculations requires a layer-by-layer description of the wall or roof, specifying the thermal properties of each layer. Heating load calculations are typically performed with the assumption that the wall or roof is in steady-state conditions, and so only the thermal resistance of the wall or roof is needed. For cooling load calculations, unsteady or dynamic heat transfer will occur, so information on the heat storage capacity of each layer is also needed. Section 3.1 provides the necessary thermal property data. Section 3.2 gives the procedure for determining U-factors of walls and roofs for cases where there are no thermal bridges. For fenestration-windows, skylights, and doors-thermal and optical properties are given in Section 3.3. For walls and roofs with thermal bridges, consult Appendix E.

### 3.1 Thermal Property Data-Walls and Roofs

### 3.1.1 Thermal Properties of Building and Insulation Materials

The basic properties that determine the way in which a material will behave in the conductive mode of heat transfer are the thermal conductivity $k$, the density $\rho$, and the specific heat capacity $C_{p}$. The last two properties are important when unsteady heat transfer is occurring because of heat storage. These variables are discussed in Chapters 7, 8, and 11, where the unsteady nature of the load is covered. The thermal conductivity is basic to the determination of the thermal resistance component leading to the U-factor.

Table 3.1 lists the basic properties for many different construction and insulation materials. The data given are intended to be representative of materials generally available and are not intended for specification purposes. It is always advisable to use manufacturers' specification data when available.

Note that the data are given in two forms-for materials that may likely be used in any thickness, the density, thermal conductivity, and specific heat are given. For materials that come in fixed thicknesses, often only the unit thermal resistance is given in the column labeled Resistance $R$.

For materials where the unit thermal resistance is not given, it may be determined by

$$
\begin{equation*}
R=x / k,\left(\mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right) / \mathrm{Btu} \tag{3.1}
\end{equation*}
$$

where
$k=$ thermal conductivity, Btu•in./h $\cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$x=$ thickness of material, in.
The thermal resistance for the wall or roof section is then the summation of all of the layer unit thermal resistances divided by the wall or roof area. The thermal resistance for the wall or roof section is then

$$
\begin{equation*}
R^{\prime}=\sum R / A,\left(\mathrm{~h} \cdot{ }^{\circ} \mathrm{F}\right) / \mathrm{Btu} \tag{3.2}
\end{equation*}
$$

The unit thermal resistance per inch of material thickness is simply the reciprocal of the thermal conductivity. It should be noted that the data of Table 3.1 are for a mean temperature of $75^{\circ} \mathrm{F}$. While these data are adequate for design load calculations, the thermal conductivity does depend on the temperature of the material.

For wall or roof constructions with an interior planar air space, thermal resistances can be found in Table 3.2, using effective emittances for the air space determined from Table 3.3a. Table 3.3b gives solar absorptance values needed for cooling load calculations as described in Section 7.3.

${ }^{\mathrm{a}}$ See Chapter 25. Thermal resistance values were determined from $R=1 / C$, where $C=h_{c}+\varepsilon_{e f f}$ $h_{r}, h_{c}$ is conduction/convection coefficient, $\varepsilon_{e f f} h_{r}$ is radiation coefficient $\approx 0.0068 \varepsilon_{e f f}\left[\left(t_{m}+\right.\right.$ $460) / 100]^{3}$, and $t_{m}$ is mean temperature of air space. Values for $h_{c}$ were determined from data developed by Robinson et al. (1954). Equations (5) to (7) in Yarbrough (1983) show data in this table in analytic form. For extrapolation from this table to air spaces less than 0.5 in . (e.g., insulating window glass), assume $h_{c}=0.159\left(1+0.0016 t_{m}\right) / l$, where $l$ is air space thickness in in., and $h_{c}$ is heat transfer through air space only.
${ }^{\mathrm{b}}$ Values based on data presented by Robinson et al. (1954). (Also see Chapter 4, Tables 5 and 6 , and Chapter 33). Values apply for ideal conditions (i.e., air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage to or from the space). This table should not be used for hollow siding or profiled cladding: see Table 1. For greater accuracy, use overall U-factors determined through guarded hot box (ASTM Standard C1363) testing. Thermal resistance values for multiple air spaces must be based on careful estimates of mean temperature differences for each air space.
${ }^{\mathrm{c}}$ A single resistance value cannot account for multiple air spaces; each air space requires a separate resistance calculation that applies only for established boundary conditions. Resistances of horizontal spaces with heat flow downward are substantially independent of temperature difference.
${ }^{\mathrm{d}}$ Interpolation is permissible for other values of mean temperature, temperature difference, and effective emittance $\varepsilon_{\text {eff }}$. Interpolation and moderate extrapolation for air spaces greater than 3.5 in . are also permissible.
${ }^{\mathrm{e}}$ Effective emittance $\varepsilon_{\text {eff }}$ of air space is given by $1 / \varepsilon_{\text {eff }}=1 / \varepsilon_{1}+1 / \varepsilon_{2}-1$, where $\varepsilon_{1}$ and $\varepsilon_{2}$ are emittances of surfaces of air space (see Table 2). Also, oxidation, corrosion, and accumulation of dust and dirt can dramatically increase surface emittance. Emittance values of $\mathbf{0 . 0 5}$ should only be used where the highly reflective surface can be maintained over the service life of the assembly.

### 3.1.2 Surface Conductance and Resistances

The transfer of heat to surfaces such as walls and roofs is usually a combination of convection and radiation. For simplified calculation methods, (e.g., the radiant time series method [RTSM]) the two modes are combined into a combined-surface conductance or thermal resistance, even though the radiation component is quite sensitive to surface type and temperature. Values of combined-surface conductances are given in Table 3.4.

The heat balance method (HBM) separates the radiative and convective heat transfer mechanisms, so the combined-surface conductance is not used. Rather, convection coefficients are determined with correlations and radiative heat transfer is analyzed with the mean radiant temperature method. These are discussed in Chapter 11.

| 15 mph wind (for winter) | Any | 6.00 | 0.17 | - | - | - | - |
| 7.5 mph wind (for summer) | Any | 4.00 | 0.25 | - | - | - | - |

Notes:

1. Surface conductance $h_{i}$ and $h_{o}$ measured in $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$; resistance $R_{i}$ and $R_{o}$ in $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$.
2. No surface has both an air space resistance value and a surface resistance value.
3. Conductances are for surfaces of the stated emittance facing virtual blackbody surroundings at same temperature as ambient air. Values based on surface/air temperature difference of $10^{\circ} \mathrm{F}$ and surface temperatures of $70^{\circ} \mathrm{F}$.
4. See Chapter 4 for more detailed information.
5. Condensate can have significant effect on surface emittance (see Table 2). Also, oxidation, corrosion, and accumulation of dust and dirt can dramatically increase surface emittance. Emittance values of 0.05 should only be used where highly reflective surface can be maintained over the service life of the assembly.

## Load Calculation Applications Manual (I-P), Second Edition

### 3.2 Calculating Overall Thermal Resistance

For building constructions made out of homogeneous layers, the overall thermal resistance is calculated by summing the individual layer resistances:

$$
\begin{equation*}
R=R_{i}+\sum_{j=1}^{N} R_{j}+R_{o} \tag{3.3}
\end{equation*}
$$

where
$R_{j}=$ the $j^{\text {th }}$ layer thermal resistance given by the ratio of the thickness to the thermal conductivity, $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$
$R_{i}=$ the inside air film thermal resistance, $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$
$R_{o}=$ the outdoor air film thermal resistance, $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$
$N=$ the number of layers in the construction
The overall heat transfer coefficient $U$ is the inverse of the overall thermal resistance:

$$
\begin{equation*}
U=\frac{1}{R} \tag{3.4}
\end{equation*}
$$

Example 3.1
Overall Thermal Resistance

Architectural plans for a building show a wall as being constructed from 4 in. face brick, 1 in. thick R- 5 extruded polystyrene insulation, and 8 in. concrete masonry unit (CMU, otherwise known as concrete block). The face brick is on the outside of the wall. The insulation is glued to the CMU, and there is an air gap (approximately 1.5 in .) between the face brick and the insulation. Find the overall thermal resistance and the U-factor for the wall under winter conditions.

Solution: The first step is to find the thermal properties of each layer in the wall. As is often the case, architectural plans do not specify the materials with enough detail to precisely select every material from Table 3.1. In this situation, some engineering judgment is required. For this wall, the overall thermal resistance will depend strongly on the insulation resistance. Fortunately, this is specified. The layers, from outside to inside, are as follows:

- The outside surface resistance, under winter conditions (assumed 15 mph wind) is taken from Table 3.4 as $0.17 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- In Table 3.1, thermal properties are given for a range of brick densities, and for every density, variation in conductivity and resistance is given. Taking a median value for density ( $110 \mathrm{lb} / \mathrm{ft}^{3}$ ), an intermediate value for conductivity for resistance would be $0.185 \mathrm{ft}^{2}{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$ per inch of brick, or 0.74 for the 4 in . thick brick layer ( 4 in . $0.185 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$ per inch of brick $=$ $\left.0.74 \mathrm{ft}^{2}{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}\right)$.
- The resistance for the air gap between the brick and the extruded polystyrene insulation can be estimated from Table 3.2. To use Table 3.2, some estimate of the thermal emittance of the two surfaces must be made. From Table 3.3a, we can see that unless the surface is a polished metal, an estimate of 0.9 for emittance is reasonable, and with both surfaces having an emittance of 0.9 , the effective emittance for the air gap is 0.82 . Returning to Table 3.2, and knowing the air gap is 1.5 in.thick, the effective emittance is 0.82 , and the direction of heat flow is horizontal, we can then choose the resistance based on an estimate of the mean temperature and temperature difference. Since we are looking at winter conditions, a mean temperature of $0^{\circ} \mathrm{F}$ or $50^{\circ} \mathrm{F}$ and a temperature difference of $10^{\circ} \mathrm{F}$ or $20^{\circ} \mathrm{F}$ might be reasonable. Note that for the entire span of these combinations, the resistance only varies between 1.02 and 1.23. This will have a small effect on the overall resistance, and therefore we may choose an intermediate value of $1.1 \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- The resistance of the insulation is known to be $5 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- For the concrete block there are even more entries in Table 3.1 than for brick. Lacking specific information for the concrete block, "normal weight aggregate" seems like a good first guess, and review of the table data for all types of unfilled block shows that its resistance $\left(1.11-0.97 \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}\right)$ is at the low end. Hence, we will not go far wrong by choosing a value from within this range, say $1.0 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- The inside surface resistance can be chosen from Table 3.4 for horizontal heat flow, nonreflective surface as $0.68 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.

The overall thermal resistance can then be determined by summing up the individual components: $R=0.17+0.74+1.1+5.0+1.0+0.68=8.69 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} /$ Btu. The U-factor is then determined as the inverse of the overall thermal resistance: $U=1 / R=1 / 8.69=0.12 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$.

With the final value in hand, we can see that small errors in the individual resistances, probably on the order of $\pm 0.1 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$, will have a fairly small influence on the U-factor. Thus, several of the informed guesses made for the individual layers have quite a small effect.

The above example is relatively straightforward because each layer has only a single material. A more common case is for one or more layers to contain multiple materials (e.g., stud and insulation). In this case, the element with the higher conductance is often referred to as a thermal bridge. For such building constructions, the effects of the thermal bridge must be taken into account (see Appendix E).

### 3.3 Thermal and Optical Property Data-Fenestration

The term fenestration refers to the openings in the building envelope, such as doors and windows. The thermal properties of doors and windows can have a significant impact on the heating load, as they typically have a much higher conductance than the walls and roof. The optical properties of windows and doors (where glazed) often have a significant impact on the cooling load due to both direct transmission of solar radiation and convection into the space of solar radiation absorbed by the window or door.

When available, manufacturers' data for windows and doors should be used. It is typical for manufacturers of windows to provide U-factors and normal solar heat gain coefficients (SHGCs) for individual products. The manufacturer's U-factor should be used for calculating conductive heat gains, and the manufacturer's SHGC should be used with the RTSM (Chapter 7) or the HBM (Chapter 11) for calculating solar heat gains. If this information is not available, this chapter provides representative thermal and optical property data for a range of fenestration products.

AIR CONDITIONING COMPANY

Tables 3.5a through Table 3.5d provide U-factors for doors that are glazed less than $50 \%$ by area. Tables 3.6 a and 3.6 b provide representative computed U-factors for a variety of generic fenestration products, including windows, skylights, and doors with glazing area in excess of $50 \%$. U-factors, particularly for windows with multiple glazing layers, will vary with temperature. The values in Tables 3.6a and 3.6b are given for heating design conditions but are adequate for cooling design conditions, as conductive heat gain is usually a small fraction of the total heat gain for windows in direct sunlight.

Most of the total heat gain for windows is due to solar radiation transmitted into the space and solar radiation absorbed by the window before flowing into the space

Notes
${ }^{a}$ Values are for both thermally broken and thermally unbroken doors. ${ }^{\mathrm{e}} \mathrm{U}$-factor determined using NFRC Technical Document 100-91. Not updated to current
${ }^{6}$ Lower values are for thermally broken doors; higher values are for doors with no rating methodology in NFRC Technical Document 100-2010. U-factor determined for thermal break.
${ }^{\mathrm{c}}$ Typical size for a small private airplane (single- or twin engine.)

## Notes:

1. All heat transmission coefficients in this table include film resistances and are based on winter conditions of $0^{\circ} \mathrm{F}$ outdoor air temperature and $70^{\circ} \mathrm{F}$ indoor air temperature, with 15 mph outdoor air velocity and zero solar flux. Except for single glazing, small changes in indoor and outdoor temperatures do not significantly affect overall U-factors. Coefficients are for vertical position except skylight values, which are for $20^{\circ}$ from horizontal with heat flow up.
2. Glazing layer surfaces are numbered from outdoor to indoor. Double, triple, and quadruple refer to number of glazing panels. All data are based on $1 / 8 \mathrm{in}$. glass, unless otherwise noted. Thermal conductivities are: $0.53 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$ for glass, and $0.11 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$ for acrylic and polycarbonate.
3. Standard spacers are metal. Edge-of-glass effects are assumed to extend over the $21 / 2 \mathrm{in}$. band around perimeter of each glazing unit.
via convection and thermal radiation. To determine this heat gain, additional thermal and optical properties are needed. Table 3.7 gives angle-dependent SHGCs, transmittances, reflectances, and absorptances for representative fenestration products. These values may be used in the HBM as explained in Chapter 11. Table 3.8 contains angle

|  |  |  |  |  |  |  |  | 8. U-factors in this table were determined using NFRC 100-91. They have not been updated to the current rating methodology in NFRC 100-2010. |  |  |  |  |  |  |
| 5. Use $U=0.6 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$ for glass block with mortar but without reinforcing or framing |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
| 6. Use of this table should be limited to that of an estimating tool for early phases of design. |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
| 7. Values for triple- and quadruple-glazed garden windows are not listed, because these are not common products. |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

correction factors that may be applied to the manufacturer's normal SHGC for use with the RTSM, as explained in Chapter 7. For windows with interior shading such as blinds and draperies, the interior attenuation coefficient (IAC), tabulated in Tables 3.9a through 3.9 g , is multiplied by the solar heat gain through an unshaded window to determine the total solar heat gain with interior shading.

IAC values are tabulated by glass type, shading type, and profile angle. The profile angle $\Omega$ for louvered or slat-type sunshades (e.g., Venetian blinds) is illustrated in Figure 3.1. The glass type will determine which of Tables 3.9a through Table 3.9f are used and, specifically, which column is selected. Then, the louver location and louver reflectance will determine which set of IACs are chosen. Within each set, several values of IAC are given for different profile angles. Computation of the profile angle

## azarnasimb

[^3]Notes: ${ }^{\text {a }}$ Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
${ }^{\mathrm{b}}$ Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to $0^{\circ}$
azarnasim

## Thermal Property Data

depends on the solar angles, which are described in Appendix D, Section D.1. For horizontal blinds, the profile angle $\Omega$ is given as

$$
\tan (\Omega)=\frac{\tan (\beta)}{\cos (\gamma)}
$$

where $\beta$ is the solar altitude angle and $\gamma$ is the surface solar azimuth angle.
For vertical blinds, the profile angle is the surface solar azimuth angle. Figure 3.1 shows the geometry assumed for the data given in the tables with the slat width $w$, slat crown $c$, slat spacing $s$, and slat angle $\phi$. The values given in the tables assume ratios $w / s$ and $w / c$ of 1.2 and 1.6 , respectively. The slat angle includes worst, where the shades are opened to maximize the solar heat gain; $0^{\circ}$; excluded beam, where the blinds are adjusted to eliminate transmission of beam radiation; $45^{\circ}$; and closed. For each combination of glass type, shade location and type, and slat angle, four values are given:

- $\mathrm{IAC}_{0}$-corresponding to a profile angle of $0^{\circ}$
- $\mathrm{IAC}_{60}$-corresponding to a profile angle of $60^{\circ}$

Figure 3.1 Geometry of Slat-Type Sunshades
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 15, Figure 18).

- $\mathrm{IAC}_{\text {diff }}$-the IAC applied to diffuse irradiation
- $F_{R}$-the fraction of the solar heat gain that is radiant

For profile angles other than $0^{\circ}$ or $60^{\circ}$, the IAC can be estimated as

$$
\begin{equation*}
\operatorname{IAC}(\theta, \Omega)=\mathrm{IAC}_{0}+\mathrm{IAC}_{x} \cdot \min (1,0.02 \cdot \Omega) \tag{3.6}
\end{equation*}
$$

where $\mathrm{IAC}_{x}=\mathrm{IAC}_{60}-\mathrm{IAC}_{0}$.
For roller blinds, insect screens, and draperies, IAC values are given in Table 3.9 g . Drapery fabrics may be characterized using Figures 3.2 and 3.3. Draperies are also characterized by their fullness- $100 \%$ fullness corresponds to the fabric (i.e., if stretched out horizontally) being twice as wide as the window; $0 \%$ fullness would correspond to the fabric being the same width as the window, such as a roller blind. The tables only treat the $100 \%$ and $0 \%$ fullness cases (i.e., draperies are assumed to have $100 \%$ fullness; roller blinds and insect screens are assumed to have $0 \%$ fullness).

NOTE: Classes may be approximated by eye. With closed fabrics, no objects are visible through the material, but large light or dark areas may show. Semiopen fabrics do not allow details to be seen, and large objects are clearly defined. Open fabrics allow details to be seen, and the general view is relatively clear with no confusion of vision. The yarn color or shade of light or dark may be observed to determine whether the fabric is light, medium, or dark.

Figure 3.2 Designation of drapery fabrics.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 15, Figure 19).

Figure 3.3 Drapery fabric properties.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 15, Figure 20).

Use of the IAC to compute solar heat gain is described in Section 7.7 of Chapter 7 and demonstrated in Example 7.2.

With the exception of Tables 3.3b and 3.8, the tables in this section all come from Chapter 15 of the ASHRAE Handbook-Fundamentals (ASHRAE 2013) and for further information the reader should consult that chapter.

## Environmental Design Conditions

This chapter describes the weather data for locations around the world (which can be found in supporting files online at www.ashrae.org/lcam), the application of the weather data, and recommended interior and exterior design conditions. The data come from the ASHRAE HandbookFundamentals (2013) and are based on long-term hourly observations. For additional information on the basis for the weather data and its application, consult Chapter 14 of the ASHRAE Handbook-Fundamentals (2013).

### 4.1 Indoor Design Conditions

The primary purpose of a heating and air-conditioning system is to maintain the space in a comfortable and healthy condition. To do this, the system must generally maintain the dry-bulb temperature and the relative humidity within an acceptable range.

ANSI/ASHRAE Standard 55-2010, Thermal Environmental Conditions for Human Occupancy, gives thermal comfort values at selected conditions in the building environment. Physiological principles, comfort, and health are addressed in Chapter 9 of the ASHRAE Handbook-Fundamentals (2013). The ASHRAE Hand-book-HVAC Applications (2011) gives specific recommendations for indoor design conditions for such applications as hospitals and other special cases.

ANSI/ASHRAE/ACCA Standard 183-2007, Peak Cooling and Heating Load Calculations in Buildings Except Low-Rise Residential Buildings, states that "Indoor design conditions shall be established by owner criteria, local codes, or comfort criteria." This gives considerable latitude in selecting design conditions. Experience has shown that, except in critical cases, the indoor design temperature and relative humidity should be selected on the high side of the comfort envelope to avoid overdesign of the system.

For cooling load calculations, a design dry-bulb temperature of $75^{\circ} \mathrm{F}$ to $78^{\circ} \mathrm{F}$ with a design relative humidity of approximately $50 \%$ is widely used in practice for usual occupied spaces. For heating load, a dry-bulb temperature of $70^{\circ} \mathrm{F}$ with relative humidity less than or equal to $30 \%$ is common.

### 4.2 Outdoor Design Conditions

The annual climatic design conditions for Atlanta, Georgia, are shown in Table 4.1 to illustrate the format of the data. Data for five additional sites are shown in Tables 4.44.8 at the end of the chapter. Data in the same format for 6443 stations worldwide are given in the online supplementary files. Not all of the data are immediately useful for design load calculations; application of the data for cooling and heating load calculations is discussed in the following sections. Data needed for load calculations are, for almost all of the stations, incorporated in the accompanying online spreadsheets. Columns are numbered and described as follows:

## Station Information

## Station Identifiers

Name of the observing station
World Meteorological Organization (WMO) station identifier
Latitude of station, ${ }^{\circ} \mathrm{N} / \mathrm{S}$
Longitude of station, ${ }^{\circ} \mathrm{E} / \mathrm{W}$

## azarnasim ${ }^{87}$

Elevation of station, ft
Standard pressure at elevation, in psia
Time zone, $\mathrm{h} \pm$ coordinated universal time (UTC)
Time zone code (e.g., NAE = Eastern Time, United States, and Canada)

- The supporting files online contain a list of all time zone codes used in the tables.
Period analyzed (e.g., 72-01 = data from 1972 to 2001 were used)
Weather Bureau Army Navy (WBAN) station identifier

## Annual Heating and Humidification Design Conditions

1a. Coldest month (i.e., month with lowest average dry-bulb temperature; 1 = January, $12=$ December)

1b. and 1c. Dry-bulb temperature corresponding to $99.6 \%$ and $99.0 \%$ annual cumulative frequency of occurrence (cold conditions), ${ }^{\circ} \mathrm{F}$

1d.-1i. Dew-point temperature corresponding to $99.6 \%$ and $99.0 \%$ annual cumulative frequency of occurrence, ${ }^{\circ} \mathrm{F}$; corresponding humidity ratio, calculated at standard atmospheric pressure at elevation of station, grains of moisture per lb of dry air; mean coincident drybulb temperature, ${ }^{\circ} \mathrm{F}$
$1 \mathrm{j} .-1 \mathrm{~m}$. Wind speed corresponding to $0.4 \%$ and $1.0 \%$ cumulative frequency of occurrence for coldest month (column 1a), mph; mean coincident dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

1n.-1o. Mean wind speed coincident with 99.6\% dry-bulb temperature (column 1b), mph; corresponding most frequent wind direction, degrees from north (east $=90^{\circ}$ )

## Annual Cooling, Dehumidification, and Enthalpy Design Conditions

2a. Hottest month (i.e., month with highest average dry-bulb temperature; 1 = January, 12 = December)

2b. Daily temperature range for hottest month, ${ }^{\circ} \mathrm{F}$ (defined as mean of the difference between daily maximum and daily minimum drybulb temperatures for hottest month [column 2a])
$2 \mathrm{c} .-2 \mathrm{~h}$. Dry-bulb temperature corresponding to $0.4 \%, 1.0 \%$, and $2.0 \%$ annual cumulative frequency of occurrence (warm conditions), ${ }^{\circ} \mathrm{F}$; mean coincident wet-bulb temperature, ${ }^{\circ} \mathrm{F}$
$2 \mathrm{i} .-2 \mathrm{n}$. Wet-bulb temperature corresponding to $0.4 \%, 1.0 \%$, and $2.0 \%$ annual cumulative frequency of occurrence, ${ }^{\circ} \mathrm{F}$; mean coincident dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

2o.-2p. Mean wind speed coincident with $0.4 \%$ dry-bulb temperature (column 2c), in mph; corresponding most frequent wind direction, degrees from north

3a. -3 i . Dew-point temperature corresponding to $0.4 \%, 1.0 \%$, and $2.0 \%$ annual cumulative frequency of occurrence, ${ }^{\circ} \mathrm{F}$; corresponding humidity ratio, calculated at the standard atmospheric pressure at elevation of station, grains of moisture per lb of dry air; mean coincident dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

Table 4.1 Design Conditions for Atlanta, Georgia
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 14, Table 1)

3j.-3o. Enthalpy corresponding to $0.4 \%, 1.0 \%$, and $2.0 \%$ annual cumulative frequency of occurrence, $\mathrm{Btu} / \mathrm{lb}$; mean coincident dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

3p. Number of hours between 8 a.m. and 4 p.m. (inclusive) with drybulb temperature between $55^{\circ} \mathrm{F}$ and $69^{\circ} \mathrm{F}$

## Extreme Annual Design Conditions

4a.-4c. Wind speed corresponding to $1.0 \%, 2.5 \%$, and $5.0 \%$ annual cumulative frequency of occurrence, mph

4d. $\quad$ Extreme maximum wet-bulb temperature, ${ }^{\circ} \mathrm{F}$
4e. -4 h . Mean and standard deviation of extreme annual maximum and minimum dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

4i.-4p. 5-, 10-, 20-, and 50-year return period values for maximum and minimum extreme dry-bulb temperature, ${ }^{\circ} \mathrm{F}$

## Monthly Design Conditions

A range of monthly design conditions for Atlanta, Georgia are provided in rows 5 through 41 of Table 4.1. These values are derived from the same analysis that results in the annual design conditions.

The monthly summaries are useful when seasonal variations in solar geometry and intensity, building or facility occupancy, or building use patterns require consideration. In particular, these values can be used when determining air-conditioning loads during periods of maximum solar heat gain. The monthly information in Table 4.1 is identified by the following column numbers:
5.-12. Monthly average temperatures, standard deviation of monthly average temperatures, both in ${ }^{\circ} \mathrm{F}$. Heating degree days for base temperatures of $50^{\circ} \mathrm{F}$ and $65^{\circ} \mathrm{F}$. Cooling degree days for base temperatures of $50^{\circ} \mathrm{F}, 65^{\circ} \mathrm{F}, 74^{\circ} \mathrm{F}$, and $80^{\circ} \mathrm{F}$. Not typically used in design load calculations.
13.-16. Monthly average precipitation, maximum, minimum, and standard deviation of precipitation, all in inches.
17.-24. Dry-bulb temperature corresponding to $0.4 \%, 2.0 \%, 5.0 \%$, and $10.0 \%$ cumulative frequency of occurrence for indicated month, ${ }^{\circ} \mathrm{F}$; mean coincident wet-bulb temperature, ${ }^{\circ}$ F. For a 30 -day month, the $0.4 \%, 2.0 \%, 5.0 \%$, and $10.0 \%$ values of occurrence represent the value that occurs or is exceeded for a total of $3,14,36$ and 72 hours, respectively, per month on average over the period of record.
25.-32. Wet-bulb temperature corresponding to $0.4 \%, 2.0 \%, 5.0 \%$, and $10.0 \%$ cumulative frequency of occurrence for indicated month, ${ }^{\circ} \mathrm{F}$; mean coincident dry-bulb temperature, ${ }^{\circ} \mathrm{F}$.
33.-37. Mean daily temperature range for month indicated, ${ }^{\circ} \mathrm{F}$ (defined as mean of difference between daily maximum/minimum dry-bulb temperatures). Mean daily dry- and wet-bulb temperature ranges coincident with the $5 \%$ monthly design dry-bulb temperature. Mean daily dry- and wet-bulb temperature ranges coincident with the $5 \%$ monthly design wet-bulb temperature.
38.-41. Clear-sky optical depths for beam (taub) and diffuse (taud) solar irradiation corresponding to the 21st day of each month. Also, clear-sky normal beam irradiation and horizontal diffuse irradiation at solar noon for the same days, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$.

Monthly percentile values of dry- or wet-bulb temperature may be higher or lower than the design conditions corresponding to the same nominal percentile, depending on the month and the seasonal distribution of the parameter at that location. Generally, for the hottest or most humid months of the year, the monthly percentile value exceeds the design condition corresponding to the same annual percentile. For example, in Table 4.1, the annual $0.4 \%$ design dry-bulb temperature (row 2, column c) in Atlanta, GA is $93.9^{\circ} \mathrm{F}$. Row 17 shows that the $0.4 \%$ monthly dry-bulb temperature exceeds $93.9^{\circ} \mathrm{F}$ for June, July, and August, with values of $94.5^{\circ} \mathrm{F}, 97.8^{\circ} \mathrm{F}$, and $97.4^{\circ} \mathrm{F}$, respectively. A general, approximate rule of thumb is that the $n \%$ annual cooling design value is roughly equivalent to the $5 n \%$ monthly cooling condition for the hottest month. For example, the $0.4 \%$ annual design dry bulb temperature is roughly equivalent to the $2 \%$ monthly design dry bulb for the hottest month.

### 4.2.1 Cooling Load Design Conditions

Design cooling load calculations are typically performed first for annual design conditions-a design day with a statistically high peak temperature. This peak day is assumed to occur in the month with the highest mean dry-bulb temperature, shown in column 2a of Table 4.1. The month information is used to determine the incident solar radiation, assuming clear-sky conditions, as described in Appendix D. The peak temperature would be the annual $0.4 \%, 1 \%$, or $2 \%$ dry-bulb temperatures shown in columns $2 \mathrm{c}, 2 \mathrm{e}$, and 2 g , respectively, of Table 4.1. The daily dry-bulb temperature range for this day is given in column 2 b and is used as described in the next section to determine the hourly dry-bulb temperatures for the design day. The mean coincident wind speed and direction corresponding to the $0.4 \%$ design condition are given in columns 2 o and 2 p and may be used to help estimate infiltration.

The above information is used to define a peak temperature design day that may often be sufficient for determining peak room cooling loads. However, peak room cooling loads may occur on days that are not peak temperature days for rooms with cooling loads dominated by solar radiation. For example, rooms with a significant amount of south-facing glass in temperate climates (e.g., Atlanta) might have peak cooling loads in the fall or winter. For this reason, peak temperatures are specified on a monthly basis, along with the mean coincident wet-bulb temperature in rows 17 to 24 . As it is difficult beforehand to know in which month the cooling load will peak, it is recommended that months other than the peak temperature month be checked for rooms with significant amounts of glazing.

Finally, although peak room cooling load generally follows either peak temperatures or peak solar gains, peak system loads can often occur at peak wet-bulb temperatures. Therefore, it may also be prudent to calculate cooling loads for design wetbulb conditions given in rows 25 to 32 of Table 4.1. Here, peak wet-bulb temperatures are given for each month, at four different percentiles. In this analysis, the peak drybulb temperature would be the mean coincident dry bulb given in rows 25 to 32 .

### 4.2.2 Daily Temperature Profiles for Cooling Load Calculations

Table 4.1 gives peak design temperatures, but cooling load calculation procedures require hourly temperatures. However, with peak design temperatures and the corresponding daily temperature range taken from Table 4.1, hourly dry-bulb temperatures can be obtained by subtracting the daily temperature range multiplied by the fractions given in Table 4.2.

For example, as shown in Table 4.1, the $1 \%$ design condition in Atlanta is $91.7^{\circ} \mathrm{F}$; the hottest month is July and the corresponding daily range (in column 2b) is $17.0^{\circ} \mathrm{F}$. From Table 4.2, the fraction of daily range at 5:00 p.m. (hour 17) apparent solar time is 0.14 , and the temperature at 5:00 p.m. would be $91.7^{\circ} \mathrm{F}-0.14 \cdot 17.0^{\circ} \mathrm{F}=89.3^{\circ} \mathrm{F}$. If, as is often the case, the load calculation is being performed on the basis of local standard time or local daylight savings time, the values in Table 4.2 can be interpolated using the corresponding apparent solar time at each hour.

Alternatively, an equation fit to the fraction-of-daily-range data in Table 4.2 can be used. This equation can be given as:

$$
\begin{equation*}
t=t_{\text {peak }}-D R \sum_{i=0}^{11}\left[a_{i} \cos \left(\frac{2 \pi i \theta}{24}\right)+b_{i} \sin \left(\frac{2 \pi i \theta}{24}\right)\right] \tag{4.1}
\end{equation*}
$$

where
$t=$ air temperature, ${ }^{\circ} \mathrm{F}$
$t_{\text {peak }}=$ peak design temperature, ${ }^{\circ} \mathrm{F}$
$D R=$ daily range, ${ }^{\circ} \mathrm{F}$
$a_{i}, b_{i}=$ equation-fit coefficients given in Table 4.3, dimensionless
$\theta=$ the apparent solar time in decimal form, dimensionless
Note that the argument for the cosine and sine functions are in units of radians. This equation has been used in the examples in Chapters 7 and 8.

| 3 | 0.002 | -0.0194 |
| 4 | 0.0104 | 0.0123 |
| 5 | -0.0041 | 0.0049 |
| 6 | 0.0025 | -0.0017 |
| 7 | -0.0004 | -0.0027 |
| 8 | -0.0038 | 0.0036 |
| 9 | -0.0003 | 0.0006 |
| 10 | 0.0032 | 0 |
| 11 | -0.0005 | 0.0002 |

Hourly wet-bulb temperatures are also needed (e.g., for calculating hourly latent loads from infiltration or outdoor ventilation air). The peak wet-bulb temperatures would be taken from rows 17 to 24 or rows 25 to 32 of Table 4.1, depending on whether the analysis is using design dry-bulb or design wet-bulb conditions. The mean coincident wet-bulb range would be taken from row 35 (for design dry-bulb conditions) or row 37 (for design wet-bulb conditions) of Table 4.1. Hourly fractions from Table 4.2 are applied to the daily temperature range to find the hourly wet-bulb temperature. Alternatively, Equation 4.1 may be used with the appropriate inputs for peak wet-bulb temperature and wet-bulb daily range. Note that the temperature ranges apply to the $5 \%$ conditions; use at other peak temperature conditions may require some engineering judgment. Specifically, the wet-bulb temperature cannot be higher than the dry-bulb temperature. Other moist air properties can be determined using a psychrometric chart or the equations in Chapter 1 of the ASHRAE Handbook-Fundamentals (2013).

### 4.2.3 Heating Load Design Conditions

Like cooling loads, heating loads are transient because outdoor conditions are continuously changing. However, during the winter months, sustained periods of very cold and cloudy weather with relatively low levels of solar radiation may occur. In this situation, heat loss from the space will be relatively constant and, in the absence of internal heat gains, is likely to peak during the early morning hours. Therefore, for design purposes, heating losses are usually estimated based on steady-state heat transfer for some reasonable design temperature and solar radiation is neglected.

The $99.6 \%$ and $99.0 \%$ design conditions are given in columns 1 b and 1 c of Table 4.1. To calculate infiltration under the minimum temperature condition, columns 1 n and 1 o provide the mean wind speed and direction coincident to the $99.6 \%$ design dry-bulb temperature in column 1b. If the peak load were dominated by infiltration, it would also be useful to perform a heating load calculation under peak wind conditions. Columns lj through 1 m provide extreme wind speeds for the coldest month, with the mean coincident dry-bulb temperatures. To calculate the maximum latent loads due to infiltration, columns 1d through 1i provide $99.6 \%$ and $99.0 \%$ dewpoint temperatures, the corresponding humidity ratios, and the mean coincident drybulb temperatures.

Minimum temperatures usually occur between 6:00 a.m. and 8:00 a.m. solar time on clear days when the daily range is greatest. Studies at several stations have found that the duration of extremely cold temperatures can continue below the $99 \%$ level for three days and below the $97.5 \%$ level for five days or more (ECP 1980; Snelling 1985; Crow 1963). This fact should be carefully considered in selecting the design temperature.

ASHRAE/IES Standard 90.1 stipulates that design temperatures shall not be less than the $99 \%$ temperatures. The mean of annual extremes, column 4 e , may be used under unusual conditions to ensure the prevention of damage to the building or its contents. Generally, it is recommended that the $99 \%$ values be used and the $99.6 \%$ and mean of extremes be reserved for exceptionally harsh cases.

Figure 4.1. Approximate groundwater temperatures ( ${ }^{\circ} \mathrm{F}$ ) in the continental United States.
(Source: ASHRAE Handbook—HVAC Applications (2011), Chapter 34, Figure 17).

### 4.2.4 Data for Ground Heat Transfer

For below-grade walls and floors, the external design temperature is different than the design air temperatures because of the heat capacity of the soil. For the procedure described in Chapter 10, the external design temperature is the ground surface temperature. The ground surface temperature varies about a mean value by an amplitude $A$, which varies with geographic location and surface cover. Therefore, suitable external design temperatures can be obtained by subtracting $A$ for the location from the mean ground temperature. The mean ground temperature may be approximated from the annual average air temperature or from well-water temperatures, which are shown in Figure 4.1 for the continental United States. The amplitude $A$ can be estimated from the map in Figure 4.2. This map is part of one prepared by Chang (1958) giving annual ranges in ground temperature at a depth of 4 in ..

Infiltration

It is practically impossible to accurately predict infiltration on theoretical grounds. However, it is possible to develop relationships to describe the general nature of the problem. With experience and some experimental data, it is possible to put these relations in convenient tablular and graphical form, which can be useful in estimating infiltration rates. Much of the following material describes how the graphs herein were made and the restrictions placed upon them.

Infiltration is caused by a greater air pressure on the outside of the building than on the inside. The amount of infiltrated air depends on this pressure difference; the number, the size, and the shape of the cracks involved; the number, the length, and the width of the perimeter gaps of windows and doors; and the nature of the flow in the crack or gap (laminar or turbulent). The relation connecting these quantities is

$$
\begin{equation*}
Q=C(\Delta p)^{n} \tag{5.1}
\end{equation*}
$$

where
$Q=$ flow rate of leaking air, cfm
$\Delta p=$ pressure difference between the inside and the outside surfaces of the building, in. of water. When the outside pressure is greater than the inside pressure, $Q$, a positive value, is the flow rate of air leaking into the building. If the inside pressure exceeds the outside pressure, $Q$ is the flow rate of exfiltrating air.
$n=$ flow exponent. If the flow in the crack is laminar, $n=1.0$; if turbulent, $n=$ 0.50 . Usually, the flow will be transitional, thus, $n$ will be between 0.5 and 1.0. Small hairline cracks tend to have values of $n$ of 0.8 to 0.9 , whereas cracks or openings of $1 / 8 \mathrm{in}$. or greater will have complete turbulent flow, thus, $n$ will be 0.5 .
$C=$ flow coefficient. $C$ is determined experimentally and includes the crack or opening size (area).
The pressure difference $\Delta p$ is given by

$$
\begin{equation*}
\Delta p=\Delta p_{s}+\Delta p_{w}+\Delta p_{p} \tag{5.2}
\end{equation*}
$$

where
$\Delta p_{s}=$ pressure difference caused by the stack effect, in. of water
$\Delta p_{w}=$ pressure difference caused by wind, in. of water
$\Delta p_{p}=$ pressure difference caused by pressurizing the building, in. of water
The pressure differences $\Delta p_{s}, \Delta p_{w}$, and $\Delta p_{p}$ are positive when, acting separately, each would cause infiltration $\left(p_{\text {out }}-p_{\text {in }}\right)>0$.

Experienced engineers and designers often estimate infiltration by the air change method. This method simply requires an estimation of the number of air changes per hour $(\mathrm{ACH})$ that a space will experience based on their appraisal of the building type, construction, and use. The infiltration rate is related to ACH and space volume as follows:

$$
\begin{equation*}
Q=\mathrm{ach} \cdot \mathrm{VOL} / 60 \tag{5.3}
\end{equation*}
$$

## Load Calculation Applications Manual (I-P), Second Edition

where
$Q \quad=$ infiltration rate, cfm
$\mathrm{VOL}=$ gross space volume, $\mathrm{ft}^{3}$
Once the flow rate of infiltration has been determined, the resulting loads can be determined as discussed in Section 5.1. To use the detailed approach represented by Equations 5.1 and 5.2, the pressure differences that drive infiltration must be determined as described in Section 5.2. Coefficients for Equation 5.1 appropriate for various infiltration paths are summarized in Section 5.3. Section 5.4 discusses considerations for low-rise buildings.

### 5.1 Infiltration and Outdoor Ventilation Air Loads

Infiltration is the uncontrolled flow of air through unintentional openings such as cracks in the walls and ceilings and through the perimeter gaps of windows and doors driven by wind, temperature difference, and internally induced pressures. The flow of the air into a building through doorways resulting from normal opening and closing also is generally considered infiltration. The flow of air leaving the building by these means is called exfiltration. There are situations where outdoor air is intentionally supplied directly to the space for ventilation purposes. In this case, the outdoor air produces a heating or cooling load on the space in the same way as infiltration air.

In most modern systems, however, outdoor air is introduced through the air heating and cooling system where it is mixed with recirculated air, conditioned, and then supplied to the space. Confusion often results when both the air from outdoors and the air supplied to the space are referred to as ventilation air. It is becoming more common to associate ventilation with indoor air quality, and this usage, which is compatible with ANSI/ASHRAE Standard 62.1-2007, Ventilation for Acceptable Indoor Air Quality, will be used herein. Ventilation is the intentional distribution of air throughout a building and is generally a mixture of filtered outdoor and recirculated air. Infiltration air produces a load on the space while the outdoor air introduced through the air heating and cooling system produces a load on the heating or cooling coil. Therefore, the load due to outdoor air introduced through the system should be considered during the psychrometric analysis when supply air quantities, coil sizes, etc. are computed. This procedure is discussed in Chapter 9 and Appendix A.

For summer conditions, the infiltrating air has to be cooled to the desired space temperature. This represents a cooling load and must be included in the room cooling load. Assuming standard air, the equation for the sensible load is

$$
\begin{equation*}
q_{s}=C_{s} Q \Delta t \tag{5.4}
\end{equation*}
$$

where
$C_{s}=$ sensible heat factor, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{cfm} \cdot{ }^{\circ} \mathrm{F} ; 1.1$ is a typical value
$\Delta t=$ temperature difference between outdoor air and indoor air, ${ }^{\circ} \mathrm{F}$
A more complete explanation of this equation, which accounts for local pressure and temperature, is given in Chapter 9. By a similar analysis, Equation 5.4 can be used to determine the heating load caused by infiltrating air. For low-humidity winter weather at standard conditions, the value of 1.10 is usually replaced by 1.08 .

For summer conditions, some of the water vapor in the infiltrating air is ultimately condensed on the cooling system coils and, thus, constitutes a part of the space-cooling load. The equation for this latent load assuming standard air is

$$
\begin{equation*}
q_{l}=C_{l} Q \Delta W \tag{5.5}
\end{equation*}
$$

where
$C_{l}=$ air latent heat factor, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{cfm} \cdot{ }^{\circ} \mathrm{F}$; a typical value is 4840
$\Delta W=$ humidity ratio difference between outdoor and indoor air, $\mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$
A complete explanation of Equation 5.5 is also given in Chapter 9.
If humidification of a space is required, such as in the heating season or to maintain higher humidities, heat must be supplied to a humidifier to vaporize the amount of water that is deficient in the infiltrating air. Equation 5.5 gives this required latent heating load for humidification, a negative number representing a heating load.

### 5.2 Determination of Pressure Differences

To use Equation 5.1, it is necessary to be able to estimate the pressure difference based on the contributions of the three components-stack effect, wind effect, and mechanical pressurization. These are discussed in Sections 5.2.1, 5.2.2, and 5.2.3.

### 5.2.1 Pressure Difference Due to Stack Effect

The stack effect occurs when the air densities are different on the inside and outside of a building. The air density decreases with increasing temperature and decreases slightly with increasing humidity. Because the pressure of the air is due to the weight of a column of air, on winter days the air pressure at ground level will be less inside the building due to warm inside air and the cold air outside the building. As a result of this pressure difference, air will infiltrate into a building at ground level and flow upward inside the building. Under summer conditions when the air is cooler in the building, outdoor air enters the top of the building and flows downward on the inside.

Under the influence of the stack effect, there will be a vertical location in the building where the inside pressure equals the outside pressure. This location is defined as the neutral pressure level of the building. In theory, if cracks and other openings are uniformly distributed vertically, the neutral pressure level will be exactly at the mid-height of the building. If larger openings predominate in the upper portions of the building, this will raise the neutral pressure level. Likewise, large openings in the lower part will lower the neutral pressure level. The neutral pressure level in tall buildings typically varies between $30 \%$ and $70 \%$ of the total building height (Tamura and Wilson 1966, 1967). Unless there is information to the contrary, it is assumed that the neutral pressure will be at the building mid-height when under the influence of the stack effect acting alone.

The theoretical pressure difference for a horizontal leak at any vertical location, neglecting vertical density gradients, resulting from the stack effect can be found using

$$
\begin{equation*}
\Delta p_{s t}=C_{1}\left(\rho_{o}-\rho\right) g\left(H_{N P L}-H\right) \tag{5.6a}
\end{equation*}
$$

or

$$
\begin{equation*}
\Delta p_{s t}=C_{l} \rho_{o}\left(\frac{T_{i}-T_{o}}{T_{i}}\right) g\left(H_{N P L}-H\right) \tag{5.6b}
\end{equation*}
$$

where
$T_{o} \quad=$ outdoor temperature, degrees R
$T_{i} \quad=$ indoor temperature, degrees R
$\rho_{o} \quad=$ outdoor air density, $\mathrm{lb} / \mathrm{ft}^{3}$
$\rho_{i} \quad=$ indoor air density, $\mathrm{lb} / \mathrm{ft}^{3}$

Figure 5.1 Winter stack effect showing theoretical pressure difference versus height.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.1).
$g \quad=$ gravitational acceleration, $32.2 \mathrm{ft} / \mathrm{s}^{2}$
$C_{1}=$ unit conversion factor $=0.00598$ (in. of water) $\mathrm{ft} \cdot \mathrm{s}^{2} / \mathrm{lb}_{\mathrm{m}}$
$H \quad=$ height above reference plane, ft
$H_{N P L}=$ height of neutral pressure level above reference plane without any other driving forces, ft

Figure 5.1 shows the stack effect pressure variations for cold outdoor air. When the outside pressure is greater than the inside pressure, as in the lower half of the building, $\Delta p_{s t}$ is positive and the airflow is into the building. When the outside temperature is greater than the inside air temperature, then the situation is reversed and $\Delta p_{s t}$ is positive for the upper half of the building.

The $\Delta p_{s t}$ given by Equation 5.6 is valid only for buildings with no vertical separations, that is, no floors-as, for example, an atrium, an auditorium, or fire stair towers. Floors in conventional buildings offer a resistance to the vertical flow of air caused by the stack effect. There are pressure drops from one story to the next. If these resistances, such as doors, can be assumed uniform for every floor, then a single correction, called the thermal draft coefficient, $C_{d}$, can be used to relate $\Delta p_{s t}$ and $\Delta p_{s}$, the actual pressure difference:

$$
\begin{equation*}
C_{d}=\left(\frac{\Delta p_{s}}{\Delta p_{s t}}\right) \tag{5.7}
\end{equation*}
$$

Figure 5.2 shows the effect of the pressure differences between floors for winter conditions. The flow of air upward through the building causes the pressure to decrease at each floor. For this reason, $\Delta p_{s}$ is less than $\Delta p_{s t}$; thus, $C_{d}$ will be a number less than 1.0. Note that the slope of the actual inside pressure curve within each floor is the same as the theoretical curve.

Equations 5.6 and 5.7 are combined to yield

$$
\begin{equation*}
\frac{\Delta p_{s}}{C_{d}}=C_{1}\left(\frac{T_{o}-T_{i}}{T_{i}}\right) \rho_{o} g\left(H_{N P L}-H\right) \tag{5.8}
\end{equation*}
$$

Figure 5.2 Winter stack effect showing actual pressure difference versus height for a 12 -story building.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.2).

Equation 5.8 is plotted in Figure 5.3 with an inside temperature of $75^{\circ} \mathrm{F}$ and $P_{b}=14.7 \mathrm{psia}$ (sea level pressure). The values of $\Delta t$ were obtained by using decreasing values of $T_{o}$ for winter conditions. Figure 5.3 can, however, be used for the summer stack effect with little loss in accuracy.

The value of the thermal draft coefficient $C_{d}$ depends on the resistance to the vertical flow of air (that is, the tightness of stair doors, etc.) and to the quantity of vertical airflow. In this last regard, the larger the vertical flow, the larger the pressure drop per floor and thus the smaller the value of $C_{d}$ (see Figure 5.3). For this reason, loose-fitting exterior walls that produce large amounts of infiltration and, thus vertical flow, tend to lower the values of $C_{d}$, whereas loose-fitting stair floors, etc. tend to raise the value of $C_{d}$ by reducing pressure drops. With no doors in the stairwells, $C_{d}$ has a value of 1.0. Values of $C_{d}$ determined experimentally for a few modern office buildings ranged from 0.63 to 0.82 (Tamura and Wilson 1967). Values of $C_{d}$ for apartment buildings are not available. However, as apartment buildings have fewer elevator shafts and leakier exteriors, resulting in higher vertical resistance and lower horizontal resistance, the values of $C_{d}$ probably will be lower than those for office buildings.

### 5.2.2 Pressure Difference Due to Wind Effect

The wind pressure or velocity pressure is given by

$$
\begin{equation*}
P_{w}=C_{2} C_{p} \rho \frac{U^{2}}{2} \tag{5.9}
\end{equation*}
$$

where
$P_{w}=$ wind surface pressure relative to outdoor static pressure in undisturbed flow, in. of water
$\rho=$ outdoor air density, $\mathrm{lb} / \mathrm{ft}^{3}$ (about 0.075)
$U=$ wind speed, mph
$C_{p}=$ wind surface pressure coefficient, dimensionless
$C_{2}=$ unit conversion factor $=0.0129$ (in. water) $\cdot \mathrm{ft}^{3} / \mathrm{lbm} \cdot \mathrm{mph}^{2}$
$C_{p}$ is a function of location of the building envelope and wind direction (see Chapter 24, ASHRAE Handbook-Fundamentals [2013]). The pressure coefficient will always have a value of less than 1.0 and can be negative when the wind causes outdoor pressures below atmospheric on some surfaces of a building.

Figure 5.3 Pressure difference due to stack effect.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.3).

Figure 5.4 Variation of surface-averaged wall pressure coefficients for low-rise buildings.
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 24, Figure 6).

Figure 5.4 gives average wall pressure coefficients for low-rise buildings (Swami and Chandra 1987). Note that the windward side corresponds to an angle of zero and the leeward side corresponds to an angle of $180^{\circ}$. The average roof pressure coefficient for a low-rise building with a roof inclined less than $20^{\circ}$ is approximately 0.5 (Holmes 1986).

An alternative approximation for the surface-averaged wall pressure coefficient for low-rise buildings (three stories or less in height) is given by

$$
\begin{equation*}
C_{p}(\theta)=0.15\left(\cos ^{2} \theta\right)^{1 / 4}+0.45(\cos \theta)-0.65\left(\sin ^{2} \theta\right)^{2} \tag{5.10}
\end{equation*}
$$

Figures 5.5 and 5.6 give average pressure coefficients for tall buildings (Akins et al. 1979). Pressure coefficient generally increases with height; however, the variation is well within the approximations of the data in general.

For nonrectangular low-rise buildings, Swami and Chandra (1988) have made recommendations for pressure coefficients. Grosso (1992) gives a more general model for determining pressure coefficients.

Figure 5.5 Surface-averaged wall pressure coefficients for tall buildings (Akins et al. 1979).
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 24, Figure 7).

Figure 5.6 Surface-averaged roof pressure coefficients for tall buildings (Akins et al. 1979).
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 24, Figure 9).

## Effective Wind Speed

The reference wind speed used to determine pressure coefficients and infiltration rates is usually the wind speed at the eave height for low-rise buildings and the building height for high-rise buildings. However, measured meteorological data are usually available at 33 ft . This wind speed needs to be corrected for reductions caused by the difference between the height where the wind speed is measured and the height of the building.

The effective wind speed $U_{H}$ can be computed from the reference wind speed $U_{m e t}$ using boundary layer theory, and an estimate of terrain effect is given by

$$
\begin{equation*}
U_{H}=U_{m e t}\left(\frac{\delta_{m e t}}{H_{m e t}}\right)^{a_{m e t}}\left(\frac{H}{\delta}\right)^{a} \tag{5.11}
\end{equation*}
$$

where
$\delta=$ boundary layer thickness of the local terrain in Table 5.1, ft
$a=$ exponent for the local terrain in Table 5.1, dimensionless
$\delta_{\text {met }}=$ boundary layer thickness for the meteorological station in Table 5.1, ft
$a_{m e t}=$ exponent for the meteorological station in Table 5.1, dimensionless
$H=$ average height above local obstacles, weighted by the area plan, ft
$H_{\text {met }}=$ the height at which the wind speed was measured, ft
The wind boundary layer thickness $\delta$ and exponent $a$ used in Equation 5.11 are determined from Table 5.1. Typical values for meteorological stations, generally measured in flat, open terrain (category 3 in Table 5.1), are $a_{m e t}=0.14$ and $\delta_{\text {met }}=900 \mathrm{ft}$. Equation 5.11 is less reliable at heights below the average obstacle height (see Chapter 24, ASHRAE Handbook-Fundamentals [2013]).

Table 5.1 Atmospheric Boundary Layer Parameters
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 24, Table 1)

| Terrain Category | Description | Exponent $\boldsymbol{a}$ | Layer <br> Thickness $\delta$, ft |
| :---: | :---: | :---: | :---: |
| 1 | Large city centers, in which at least $50 \%$ of buildings are higher than 70 ft , over a distance of at least 0.5 mi or 10 times the height of the structure upwind, whichever is greater | 0.33 | 1500 |
| 2 | Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger, over a distance of at least 0.5 mi or 10 times the height of the structure upwind, whichever is greater | 0.22 | 1200 |
| 3 | Open terrain with scattered obstructions having heights generally less than 30 ft , including flat open country typical of meteorological station surroundings | 0.14 | 900 |
| 4 | Flat, unobstructed areas exposed to wind flowing over water for at least 1 mi , over a distance of 1500 ft or 10 times the height of the structure inland, whichever is greater | 0.10 | 700 |

AIR CONDITIONING COMPANY

## Calculation of Wind Pressure Difference

The wind-induced pressure difference is found using the coefficient:

$$
\begin{equation*}
C_{p(i n-\text { out })}=C_{p}-C_{i n} \tag{5.12}
\end{equation*}
$$

For uniformly distributed air leakage sites in all walls, $C_{\text {in }}$ is about -0.2 . Then, the wind-induced pressure difference is given by

$$
\begin{align*}
\Delta P_{w} & =C_{2} C_{p(\text { in-out })} \rho \frac{U_{H}^{2}}{2} \\
\Delta P_{w} & =C_{p(\text { in-out })} \rho \frac{U_{H}^{2}}{2} \tag{5.13}
\end{align*}
$$

### 5.2.3 Pressure Difference Due to Building Pressurization

The pressure inside a building $p_{p}$ and the corresponding pressure difference $\Delta p_{p}$ depend on the air distribution and ventilation system design and are not a result of natural phenomena. A building can be pressurized by bringing in more outdoor air through the air-handling system than is allowed to exhaust. This results in a negative pressure difference $\Delta p_{p}$ and a reduction in infiltration from wind and stack effect. On the other hand, adjustment or design of the air-handling system may be such that more air is exhausted than supplied from outdoors. This generally results in a lower pressure inside the building, a positive pressure difference $\Delta P_{p}$, and increased infiltration from wind and stack effect. This latter case is usually undesirable.

Although building pressurization often is desired and assumed to occur, it is emphasized that the air circulation system must be carefully designed and adjusted in the field to achieve this effect. For purposes of design calculations, the designer must assume a value for $\Delta P_{p}$. Take care to assume a realistic value that can actually be achieved by the system.

## Example 5.1

 Estimating Building Pressure DifferencesEstimate the indoor/outdoor pressure differences for the first and twelfth floors of a 12 -story office building located in Atlanta, Georgia, under $99.6 \%$ design heating conditions. A plan view of the building is shown in Figure 5.7. It is 120 by 30 ft with floor-to-floor heights of 10 ft . Consider only wind and stack effect - with limited information available, assume neutral pressure level at $1 / 2$ of building height. The indoor design temperature is $70^{\circ} \mathrm{F}$. The building is in a suburban area, with mixed single family dwellings, single-story retail buildings, and small office buildings.

Figure 5.7 Building orientation and wind direction for Example 5.1.

## Solution:

| Item | Equation/Figure | Explanation |
| :---: | :---: | :---: |
| Building height, ft |  | 120.0 |
| Neutral pressure height, ft |  | 60.0 |
| Wind speed, mph | Table 4.1 | 11.9 |
| Outdoor air temperature, ${ }^{\circ} \mathrm{F}$ |  | 21.5 |
| Indoor air temperature, ${ }^{\circ} \mathrm{F}$ |  | 70.0 |
| $H$ (application height of the first floor), ft |  | 5.0 |

| Roof, slope less than $20^{\circ}$, of water |  | $\Delta p=-0.082$ |

Note: Results show that air will tend to infiltrate on the first nine floors on the windward side. The first floor will have infiltration on all sides and the twelfth floor will have exfiltration on all sides. Recall that these calculations are based on a relatively low wind velocity. A higher wind velocity could cause infiltration on the top floor.

### 5.3 Infiltration Through Building Envelope

With the pressure differences established, infiltration through the building envelope can be estimated. Different approaches, as discussed below, are used for curtain walls, cracks, and operable doors.

## azarñosim

### 5.3.1 Curtain Wall Infiltration per Floor or Room

For purposes of design load calculations, it is desirable to have the infiltration rate for each room or floor of the building. Depending on the location of the room, with respect to the wind direction and the neutral pressure level, air may be infiltrating or exfiltrating. By estimating the pressure differential between inside and outside, the direction of the air leakage may be determined. It is possible that air leaking into the building on one floor may leave the building on a different floor. For the space to be comfortable, it must be assumed that the load due to infiltration is absorbed in the space where the air enters. Therefore, exfiltration does not directly cause a load and only infiltration is of interest in this regard. It is possible that some exfiltrated air enters the space by way of the air-conditioning system, but the load is absorbed by the heating or cooling coil. Calculation aids and procedures are described below. It is assumed that curtain walls are used in high-rise construction.

The flow coefficient $C$ in Equation 5.1 has a particular value for each crack and each window and door perimeter gap. Although values of $C$ are determined experimentally for window and door gaps, this same procedure will not work for cracks. Cracks occur at random in fractures of building materials and at the interface of similar or dissimilar materials. The number and size of the cracks depend on the type of construction, the workmanship during construction, and the maintenance of the building after construction. To determine a value of $C$ for each crack would be impractical; however, an overall leakage coefficient can be used by changing Equation 5.1 into the following form:

$$
\begin{equation*}
Q=K A(\Delta p)^{n} \tag{5.14}
\end{equation*}
$$

where
$A=$ wall area, $\mathrm{ft}^{2}$
$K=$ leakage coefficient $(C=K A)$
When Equation 5.14 is applied to a wall area having cracks, the leakage coefficient $K$ can then be determined experimentally. If very large wall areas are used in the test, the averaging effect of a very large number of cracks is taken advantage of. Tests have been made on entire buildings by pressurizing them with fans. Measurements are made of the flow through the fan, which is equal to the exfiltration, and the pressure difference due to pressurization (Shaw et al. 1973; Tamura and Shaw 1976). Air leakage through doors and other openings is not included in the wall leakage. Seven tall office-type buildings tested were of curtain wall construction of metal or precast concrete panels and had nonoperable windows. The results of these tests are presented in Table 5.2 and Figure 5.8. The equation of the three curves in Figure 5.8 is $Q / A=K(\Delta p)^{0.65}$ for $K=0.22,0.66$, and 1.30 . One masonry building was tested and was found to obey the relation $Q / A=4(\Delta p)^{0.65}$, which is for a very loose-fitting wall. Because only one such building was tested, this equation was not plotted in Figure 5.8.

Table 5.2 Curtain Wall Classification
(Source: Cooling and Heating Load Calculation Principles, Table 6.1)

| Leakage Coefficient | Description | Curtain Wall Construction |
| :---: | :---: | :---: |
| $K=0.22$ | Tight-fitting wall | Constructed under close supervision of work- <br> manship on wall joints. When joints seals appear <br> inadequate, they must be redone. |
| $K=0.66$ | Average-fitting wall | Conventional construction procedures are used. <br> $K=1.30$ |
| Loose-fitting wall | Poor construction quality control or an older <br> building having separated joints. |  |

(Source: Cooling and Heating Load Calculation Principles, Figure 6.5).

## Example 5.2

 Infiltration Through Curtain Wall-High RiseEstimate the curtain wall infiltration rate for the first and twelfth floors of the building described in Example 5.1. The curtain wall may be classified as "averagefitting."

Solution:

| Item | Figure/Equation | Explanation |
| :---: | :---: | :---: |
| Infiltration rate | Figure 5.8 | $Q=(Q / A) A$ |
| First floor |  | $A=$ wall surface area |
|  |  | From Example 5.1, $\Delta p_{1}$ indicates air will infiltrate on all sides |
|  | Figure 5.8 | North wall (windward): |
|  |  | $\Delta p_{1}=0.0687$ of water |
|  | Table 5.2 | $K=0.66$ |
|  | Equation 5.14 | $(Q / A)_{n}=0.116 \mathrm{cfm} / \mathrm{ft}^{2}$ |
|  |  | $A=120 \cdot 10=1200 \mathrm{ft}^{2}$ |
|  |  | $Q_{n}=0.116 \cdot 1200=138.9 \mathrm{cfm}$ |
|  |  | West wall (windward): |
|  |  | $\Delta p_{1}=0.0674$ of water, $K=0.66$ |
|  |  | $(Q / A)_{w}=0.114 \mathrm{cfm} / \mathrm{ft}^{2}$ |

$A=30 \cdot 10=300 \mathrm{ft}^{2}$
$Q_{w}=0.114 \cdot 300=34.3 \mathrm{cfm}$
South wall (leeward):
$\Delta p_{1}=0.0522$ of water, $K=0.66$
$(Q / A)_{s}=0.097 \mathrm{cfm} / \mathrm{ft}^{2}$
$A=120 \cdot 10=1200 \mathrm{ft}^{2}$
$Q_{s}=0.097 \cdot 1200=116.2 \mathrm{cfm}$
East wall (leeward):
$\Delta p_{1}=0.0517$ of water, $K=0.66$
$(Q / A)_{e}=0.096 \mathrm{cfm} / \mathrm{ft}^{2}$
$A=30 \cdot 10=300 \mathrm{ft}^{2}$
$Q_{e}=0.096 \cdot 300=28.9 \mathrm{cfm}$
$Q_{1}=Q_{n}+Q_{w}+Q_{s}+Q_{1}$
$Q_{1}=138.9+34.3+116.2+28.9=$
318.3 cfm

### 5.3.2 Crack Infiltration for Doors and Movable Windows

Door infiltration depends on the type of door, room, and building. In residences and small buildings where doors are used infrequently, the air changes associated with a door can be estimated based on air leakage through cracks between the door and the frame. Infiltration through windows and all types of doors can be determined by altering Equation 5.1 to the form

$$
\begin{equation*}
Q=K P(\Delta p)^{n} \tag{5.15}
\end{equation*}
$$

where
$P=$ perimeter of the window or door, ft
$K=$ perimeter leakage coefficient, $C=K P$
Experiments may be carried out on windows and residential-type doors, and the values of the leakage coefficient $K$ and the exponent $n$ are determined using Equation 5.15. The results of some tests are presented in Tables 5.3 and 5.4 and Figure 5.9 (Sabine and Lacher 1975; Sasaki and Wilson 1965). The equation of the three curves in Figure 5.9 is $Q / P=K(\Delta P)^{0.65}$ for $K=1.0,2.0$, and 6.0. In using Tables 5.3 and 5.4 to select the proper category, remember that movable sashes and doors will develop larger cracks over the life of the unit. Therefore, care should be taken to select a category representative of the period over which the unit will be used.

Figure 5.9 Window and door infiltration characteristics.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.9).
Table 5.3 Windows Classification
(Source: Cooling and Heating Load Calculation Principles, Table 6.2)

|  | Wood Double-Hung (Locked) | Other Types |
| :---: | :---: | :---: |
| Tight-fitting window, $K=1.0$ | Weatherstripped average gap <br> (1/64 in. crack) | Wood casement and awning windows; weatherstripped. <br> Metal casement windows; weatherstripped |
| Average-fitting window, $K=2.0$ | Nonweatherstripped <br> average gap <br> (1/64 in. crack) <br> or <br> Weatherstripped large gap <br> (3/32 in. crack) | All types of vertical and horizontal sliding windows; weatherstripped. Note: If average gap ( $1 / 64$ in. crack) this could be tight-fitting window. <br> Metal casement windows; nonweatherstripped. Note: If large gap (3/32 in. crack) this could be a loose-fitting window. |
| Loose-fitting window, $K=6.0$ | Nonweatherstripped large gap (3/32 in. crack) | Vertical and horizontal sliding windows, nonweatherstripped. |

Table 5.4 Residential-Type Door Classification
(Source: Cooling and Heating Load Calculation Principles, Table 6.3)

Tight-fitting door, $k=1.0$

Average-fitting door, $k=2.0$

Loose-fitting door, $k=6.0$

Very small perimeter gap and perfect fit weatherstripping-often characteristic of new doors.

Small perimeter gap having stop trim fitting properly around door and weatherstripped.
Large perimeter gap having poor fitting stop trim and weatherstripped, or small perimeter gap with no weatherstripping.

### 5.3.3 Infiltration Through Commercial-Type Doors

Commercial-type doors differ from those described in Section 5.6 in that they have larger cracks and they are used more often. Therefore, different data are required.

## Swinging Doors

Data for swinging doors are given in Figure 5.10 where $Q / P=K(\Delta P)^{0.50}$ for $K=20,40,80$, and 160 . The corresponding crack width is given opposite each value of $K$. Note that for these large cracks the exponent $n$ is 0.50 .

Figure 5.10 Infiltration through closed swinging door cracks.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.10).

Figure 5.11 Swinging door infiltration characteristics with traffic.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.11).

Commercial buildings often have a rather large number of people entering and leaving, which can increase infiltration significantly. Figures 5.11 and 5.12 have been developed to estimate this kind of infiltration for swinging doors. The infiltration rate per door is given in Figure 5.11 as a function of the pressure difference and a traffic coefficient that depends on the traffic rate and the door arrangement. Figure 5.12 gives the traffic coefficients as a function of the traffic rate and two door types. Single-bank doors open directly into the space; however, there may be two or more doors at one location. Vestibule-type doors are best characterized as two doors in series so as to form an air lock between them. These doors often appear as two pairs of doors in series, which amounts to two vestibule-type doors.

The equation for the four curves in Figure 5.11 is $Q=C(\Delta P)^{0.5}$ for flow coefficients $C=2500,5000,10,000$, and 15,000 . This is the same equation as would be used for flow through a sharp-edged orifice. These values of $C$ in Figures 5.11 and 5.12 were obtained from model tests and observing traffic under actual conditions (Min 1958). The values of $C$ obtained from Figure 5.12 are based on a standard-sized ( $3 \cdot 7 \mathrm{ft}$ ) door. Care must be taken to not overestimate the traffic rate. The traffic rate may be extremely high for short periods of time and not representative of most of the day.

## Revolving Doors

Figure 5.13 shows the infiltration due to a pressure difference across the door seals of a standard-sized revolving door (Schutrum et al. 1961). The results are for seals that are typically worn but have good contact with adjacent surfaces.

Figures 5.14 and 5.15 account for infiltration due to a mechanical interchange of air caused by the rotation of the standard-sized door (Schutrum et al. 1961). The amount of air interchanged depends on the inside-outside temperature difference and the rotational speed of the door.

The total infiltration is the infiltration due to leakage through the door seals plus the infiltration due to the mechanical interchange of air due to the rotation of the door.

## Air Leakage Through Automatic Doors

Automatic doors are a major source of air leakage in buildings. For automatic doors, because the opening area changes with time, a combined coefficient that accounts for the discharge coefficient and the fraction of time the door remains open

Figure 5.15 Infiltration for manually operated revolving door.
(Source: Cooling and Heating Load Calculation Principles, Figure 6.15).
was developed by Yuill et al. (2000). This is related to the people use rate per hour, as is shown in Figure 5.16. The infiltration rate is given as

$$
\begin{equation*}
Q=C_{A} A \sqrt{\Delta p} \tag{5.16}
\end{equation*}
$$

where
$Q=$ airflow rate, cfm
$C_{A}=$ airflow coefficient from Figure $5.16, \mathrm{cfm} /\left(\mathrm{ft}^{2}[\mathrm{in} \text {. of water }]^{0.5}\right)$
$A=$ area of the door, $\mathrm{ft}^{2}$
$\Delta p=$ pressure difference across the door, in. of water

## Example 5.3

Infiltration Through Swinging Commercial-Type Door

The 12 -story office building described in Example 5.1 has a two-door vestibuletype entrance on the north side (windward side) of the building. The two doors handle 500 people per hour during afternoon hours. There is a $1 / 8 \mathrm{in}$. perimeter air gap around each door. The doors have dimensions of 3.7 ft . Estimate the infiltration rate for the entrance.

Solution:

| Item | Figure/Example | Explanation |
| :---: | :---: | :---: |
| Crack infiltration |  | $Q=(Q / L) L$ |
|  | Equation 5.15 | $Q=(Q / L) L=L K(\Delta P)^{n}, n=0.50$ |
| Pressure difference | Example 5.1 | $\Delta p_{w}=0.0687$ of water (wind side) |
|  | Figure 5.10 | $K=40.0$ |
|  | Equation 5.15 or Figure 5.10 | $Q / L=40.0(0.0687)^{0.50}=10.5 \mathrm{cfm} /$ |
| Crack length |  | $L=2(7+3) \cdot 2=40 \mathrm{ft}$ |
| Crack infiltration |  | $Q_{c}=10.5 \cdot 40=419.3 \mathrm{cfm}$ |
|  |  | Note: Since doors are vestibuletype, crack infiltration will be reduced; assume $30 \%$ reduction, $Q_{c}=0.7 \cdot 419.3=293.5 \mathrm{cfm}$ |
| Infiltration due to traffic | Figure 5.12 | 250 people per door, vestibule-type |
|  |  | $C=3400$ |

$$
\Delta p=0.0687 \text { of water, } C=3400
$$

$$
Q / \text { door }=890 \mathrm{cfm}
$$

$$
\begin{aligned}
& \text { For } 2 \text { doors, } Q_{t}=890 \cdot 2=1780 \\
& \text { cfm }
\end{aligned}
$$

Total infiltration

$$
Q=Q_{c}+Q_{t}
$$

$$
Q=290+1780
$$

$$
Q=2070 \mathrm{cfm}
$$

### 5.4 Infiltration for Low-Rise Buildings

Low-rise buildings do not often utilize curtain-wall construction. This is especially true of light commercial structures where frame or masonry construction is prevalent. These structures often have movable windows, have cracks or other openings in the ceiling, and generally resemble residential construction. Stack effect, although present, is much less important than the wind in producing infiltration. Therefore, stack effect can be neglected in most cases. The air distribution systems used in light commercial buildings usually will not pressurize the space. Therefore, infiltration must be considered.

It is common practice to use the air change method, previously discussed, where a reasonable estimate of the air changes per hour $(\mathrm{ACH})$ is made based on experience. The range is usually from about 0.3 to 1.5 ach . Newer, well-constructed buildings tend to be at the lower end of the range; older buildings tend to be at the higher end.

Example 5.4 Infiltration Through Revolving Doors

Assume the door system of Example 5.3 is replaced by a manually operated revolving door, and estimate the infiltration rate.

## Solution:

| Item | Figure/Example | Explanation |
| :---: | :---: | :---: |
| Crack infiltration | Figure 5.13 | $Q_{c}=(Q /$ door $) \cdot 1$ |
|  | Example 5.1 | $\Delta p=0.0687$ of water |
|  | The lower end of the curve is used. | $Q_{c}=100 \mathrm{cfm}$ |
| Infiltration due to traffic | Figure 5.15 | 500 people $/$ hour |
|  |  | $\Delta t=48.5^{\circ} \mathrm{F}$ |
|  |  | $Q /$ door $=450 \mathrm{cfm}$ |
| $Q_{t}=450 \mathrm{cfm}$ |  |  |
| Total infiltration |  | $Q=Q_{c}+Q_{t}=100+450$ <br> $Q=550 \mathrm{cfm}$ |

A method similar to that described for curtain walls can be applied to this class of buildings where the infiltration rate is related to crack length and size. Considerable data are available for the cracks associated with windows and doors (Figures 5.9 and 5.10), but other cracks, such as those around electrical outlets, between the floor and the wall, etc., are very difficult to identify and describe.

A suggested approach to estimating infiltration in low-rise, light, commercial buildings by the crack method follows.

Assume that air infiltrates on all sides and exfiltrates through ceiling openings and cracks near the ceiling. Base the crack length on double the identifiable cracks around windows and doors to account for other obscure cracks. Compute the pressure difference based on wind alone for the windward side, but use the same value on all sides because the wind direction will vary randomly. Compute the infiltration for each room as $Q=(Q / P) P$, where $Q / P$ is obtained from data given in Section 5.6 and $P$ is crack length. Finally, check the results to see if the ACH are between about 0.5 and 2.0 to be sure of a reasonable result.

For cases where the air-moving system does have provisions for makeup and exhaust, it is good practice to consider the effect on infiltration. Obviously, if the system does pressurize the space, infiltration will be greatly reduced or eliminated. On the other hand, separate exhaust fans in restrooms, kitchens, or other spaces without suitable makeup air may reduce the space pressure and increase infiltration significantly. Such situations must be evaluated individually.

Estimate the design infiltration rate for a $20 \cdot 20 \mathrm{ft}$ room with an 8 ft ceiling in the northwest corner of a light commercial building, as shown in Figure 5.17. The room has four average-fitting $(K=2.0) 3 \cdot 5 \mathrm{ft}$ movable-sash windows with weather stripping. Two windows are on the north wall and two windows are on the west wall. The environmental conditions are those given in Example 5.1, and the wind speed from Example 5.1 for the first floor ( 5.7 mph ) may be used. The building is not pressurized.

Figure 5.17 Northwest corner zone with two exterior façades.

Solution:

| Items | Equation / Figure | Explanation |
| :---: | :---: | :---: |
| Building height, ft |  | 10.0 |
| Wind speed (at the walls), mph | Example 5.1 | 5.7 |
| Surface Average Pressure Coefficients |  |  |
| Wind-induced internal pressure coefficient |  | Assumes equal wind induced internal pressure coefficient. $C_{t n}=-0.200$ |
| Surface Average Pressure Coefficients, Low-Rise Building |  |  |
| Windward, (-) | Figure 5.4 | $C_{P W}=0.350$ |
| Effective average surface pressure coefficient | Equation 5.12 | $C_{p}=C_{\text {pout }}-C_{\text {in }}$ |
| Windward, (-) |  | $C_{P w}=0.550$ |
| Wind pressure difference calculation | Equation 5.13 | $\Delta P_{w}=C_{2} C_{p} \rho U^{2 / 2}$ |
| Average air density, $\mathrm{lb}_{\mathrm{m}} / \mathrm{ft}^{3}$ |  | $\rho=0.0753$ |
| Unit conversion factor, in. of water, $\mathrm{ft} \cdot \mathrm{s}^{2} / \mathrm{lb}_{\mathrm{m}}$ |  | $C_{2}=0.0129$ |
| Wind pressure difference (first floor) |  |  |
| Windward | Equation 5.13 | $\Delta P_{w}=0.0086 \mathrm{in}$. of water |

azar ${ }^{123}$ asim

[^7]| Infiltration data | Figure 5.9 | Assume: average-fitting windows, $K=2.0$ |
| :---: | :---: | :---: |
| Pressure difference |  | $\Delta P_{w}=0.00864$ (windward) |
| Infiltration rate | Equation 5.15 | $Q=(Q / L) L=L K(\Delta P)^{n}, n=0.65$ |
|  |  | $K=2.0$ |
|  | Equation 5.15 or Figure 5.9 | $\begin{aligned} & Q / L=2.0(0.0086)^{0.65} \\ & =0.09 \mathrm{cfm} / \mathrm{ft} \end{aligned}$ |
| Crack length per window |  | $L=2 \mathrm{H}+3 \mathrm{~W}$ |
|  |  | $=(2 \cdot 5)+(3 \cdot 3)=19 \mathrm{ft}$ |
| Total crack length |  | $\mathrm{TL}=4 \cdot \mathrm{~L} \cdot 2$ (taking double the identifiable crack length) |
|  |  | $=152 \mathrm{ft}$ |
| Infiltration rate |  | $\begin{aligned} & Q=(Q / L) L_{t}=0.09 \cdot 152 \\ & =13.8 \mathrm{cfm} \end{aligned}$ |
| ACH |  | ach $=Q /($ Volume $/ 60)$ |
|  |  | $\begin{aligned} & =13.8 \cdot 60 /(20 \cdot 20 \cdot 8) \\ & =0.26 \mathrm{ach} \end{aligned}$ |

Internal sources of heat energy may contribute significantly to the total heat gain for a space. In the case of a completely isolated interior room, the total heat gain is due entirely to internal sources. These internal sources fall into the general categories of people, lights, and equipment, such as office equipment, cooking appliances, hospital equipment, and powered machinery.
For people and some types of equipment, the heat gain may be made up of sensible and latent portions. The latent portion is generally assumed to instantaneously become part of the latent cooling load. The sensible heat gain is usually made up of both radiative and convective fractions. While the convective fraction becomes part of the cooling load instantaneously, the radiant fraction interacts with surfaces in the zone and may be absorbed and then later convected to the room air. In the radiant time series method (RTSM), the entire radiant fraction of the heat gain eventually appears as a cooling load distributed over the 24 -hour period. In the heat balance method (HBM), all or almost all of the radiant heat gains will eventually appear as cooling loads, depending on the thermal response characteristics of the zone. In contrast to the RTSM, in the HBM there is the possibility that part of the radiant heat gains will be conducted to the outside environment. This limitation in the RTSM sometimes leads to slight overpredictions of peak cooling load by the RTSM.

Both the HBM and the RTSM rely on estimated radiative/convective splits to characterize the contribution of internal heat gains to the radiant exchange. Accordingly, in addition to information about the quantity of heat gain, the radiative/convective split is also important. For lighting, the split between short-wavelength and long-wavelength radiation has some effect on the peak cooling load, but it is typically ignored. The distribution of internal radiant heat gains to the various room surfaces also has an effect, but it is typically assumed to be distributed uniformly by area to all internal surfaces.

Failure to identify all internal heat sources can lead to gross undersizing, while an overly conservative approach may lead to significant oversizing. Both cases are undesirable. The most serious problem in making accurate estimates of internal heat gain is lack of information on the exact schedule of occupancy, light usage, and equipment operation.

For example, it may not be reasonable to assume that all occupants are present, all lights are on, and all equipment is operating in a large office building. However, for a particular room in the building, the total occupancy, light, and equipment load usually should be used to compute the room's heat gain. In brief, it is probable that any particular room will be fully loaded but the complete building will never experience a full internal load. The assumption here is that the air-cooling and delivery systems would be sized to accommodate the space loads, but the central cooling plant would be sized for a lower capacity, based on the diversified load. Every building must be examined using available information, experience, and judgment to determine the internal load diversity and schedule.

## People

The heat gain from human beings has two components, sensible and latent. The total and relative amounts of sensible and latent heat vary depending on the level of activity, and in general, the relative amount of latent heat gain increases with the level of activity. Table 6.1 gives heat gain data from occupants in conditioned spaces. The latent heat gain is assumed to instantly become cooling load, while the sensible heat gain is partially delayed, depending on the nature of the conditioned space. This delay depends on the radiative and convective fractions. Typical radiative fractions are given in Table 6.1; the remainder of the sensible heat gain will be convective.

AIR CONDITIONING COMPANY

## Lighting

Since lighting is often the major internal load component, an accurate estimate of the space heat gain it imposes is needed. The rate of heat gain at any given moment can be quite different from the heat equivalent of power supplied instantaneously to those lights.

The primary source of heat from lighting comes from the light-emitting elements, or lamps, although significant additional heat may be generated from associated components in the light fixtures housing such lamps. Generally, the instantaneous rate of heat gain from electric lighting may be calculated from

$$
\begin{equation*}
q_{e l}=3.41 W F_{u l} F_{s a} \tag{6.1}
\end{equation*}
$$

where
$q_{e l}=$ heat gain, Btu/h
$\mathrm{W}=$ total installed light wattage, W
$F_{u l}=$ use factor, ratio of wattage in use to total installed wattage
$F_{s a}=$ special allowance factor $3.41=$ conversion factor, W to $\mathrm{Btu} / \mathrm{h}$
The total light wattage is obtained from the ratings of all lamps installed, both for general illumination and for display use.

Notes:

1. Tabulated values are based on $75^{\circ} \mathrm{F}$ room dry-bulb temperature. For $80^{\circ} \mathrm{F}$ room dry bulb, the total heat remains the same, but the sensible heat values should be decreased by approximately $20 \%$ and the latent heat values increased accordingly.
2. Also refer to the ASHRAE Handbook-Fundamentals (2013), Chapter 9, Table 4, for additional rates of metabolic heat generation.
3. All values are rounded to the nearest $5 \mathrm{Btu} / \mathrm{h}$.
${ }^{\text {a }}$ Adjusted heat gain is based on normal percentage of men, women, and chilAdjusted heat gain is based on normal percentage of men, women, and chil-
dren for the application listed, and assumes that gain from an adult female is $85 \%$ of that for an adult male and gain from a child is $75 \%$ of that for an adult male.
${ }^{\mathrm{b}}$ Values approximated from data in the ASHRAE Handbook-Fundamentals (2013), Chapter 9, Table 6, where $V$ is air velocity with limits shown in that table.
${ }^{\mathrm{c}}$ Adjusted heat gain includes $60 \mathrm{Btu} / \mathrm{h}$ for food per individual ( $30 \mathrm{Btu} / \mathrm{h}$ sensible and $30 \mathrm{Btu} / \mathrm{h}$ latent).
${ }^{\mathrm{d}}$ Figure one person per alley actually bowling and all others as sitting ( $400 \mathrm{Btu} / \mathrm{h}$ ) or standing or walking slowly ( $550 \mathrm{Btu} / \mathrm{h}$ ).

The use factor is the ratio of the wattage in use, for the conditions under which the load estimate is being made, to the total installed wattage. For commercial applications such as stores, the use factor would generally be unity.

The special allowance factor is the ratio of the power consumption of the lighting fixture, including lamps and ballast, to the nominal power consumption of the lamps. For incandescent lights, the special allowance factor is one. For fluorescent lights, the special allowance factor accounts for the power consumed by the ballast as well as the effect of the ballast on the lamp power consumption. The special allowance factor can be less than one for electronic ballasts that lower the electricity consumption below the rated power consumption for the lamp. It is suggested that engineers use manufacturer values for system (lamps + ballast) power, when available.

For high-intensity discharge lamps (e.g., metal halide, mercury vapor, and highand low-pressure sodium vapor lamps), the actual lighting system power consumption should be available from the manufacturer of the fixture or ballast. At the time of writing, a very limited check of ballasts available for metal halide and high-pressure sodium vapor lamps showed special allowance factors ranging from about 1.3 for low-wattage lamps down to 1.1 for high-wattage lamps.

An alternative procedure is to estimate the lighting heat gain on a per-square foot basis. Such an approach may be required when final lighting plans are not available. Table 6.2 shows the maximum lighting power density (lighting heat gain per square foot) permitted by ASHRAE/IES Standard 90.1-2010 for a range of space types. There are several cases where these values may be exceeded; examples include the following:

- Decorative lighting or lighting for highlighting art or exhibits, which may add additional heat gain
- Retail sales display areas, for which additional allowances depend on the type of merchandise
- Spaces with extra lighting controls
- Corridors and transition spaces with widths less than 8 feet

For more detailed information, consult Chapter 9 of ASHRAE/IESNA Standard 90.1-2010.

In addition to determining the lighting heat gain, the fraction of the lighting heat gain that enters the conditioned space may need to be distinguished from the fraction that enters an unconditioned space (e.g., return air plenum) and, of the lighting heat gain that enters the conditioned space, the distribution between radiative and convective heat gain must be established.

ASHRAE RP-1282 (Fisher and Chantrasrisalai 2006) experimentally studied 12 luminaire types and recommended 5 different categories of luminaires, as shown in Table 6.3. This table provides a range of design data for the conditioned space fraction, the shortwave radiative fraction, and the longwave radiative fraction under typical operating conditions: airflow rate of $1 \mathrm{cfm} / \mathrm{ft}$, supply air temperature between $59^{\circ} \mathrm{F}$ and $62^{\circ} \mathrm{F}$, and room air temperature between $72^{\circ} \mathrm{F}$ and $75^{\circ} \mathrm{F}$. The recommended fractions in Table 6.3 are based on lighting heat input rates ranging from $0.9 \mathrm{~W} / \mathrm{ft}^{2}$ to 2.6 W/ft ${ }^{2}$. For design power input higher than $2.6 \mathrm{~W} / \mathrm{ft}^{2}$, the lower bounds of the space and shortwave fractions should be used, and for design power input less than $0.9 \mathrm{~W} / \mathrm{ft}^{2}$, the upper bounds of the space and shortwave fractions should be used. The space fraction in the table is the fraction of lighting heat gain that goes to the room; the fraction going to the plenum can be computed as one minus the space fraction. The radiative fraction is the fraction of the lighting heat gain that goes to the room that is radiative. The convective fraction of the lighting heat gain that goes to the room is one minus the radiative fraction. Using values in the middle of the range yields suffi-
ciently accurate results. However, selection of values that better suit a specific situation may be determined according to notes given in the Notes column in Table 6.3.

The data presented in Table 6.3 are applicable for both ducted and nonducted returns. However, the application of the data, particularly the ceiling plenum fraction, may vary for different return configurations. For instance, for a room with a ducted return, although a portion of the lighting energy initially dissipated to the ceiling plenum is quantitatively equal to the plenum fraction, a large portion of this energy would likely end up as the conditioned space cooling load. A small portion would end

up as the cooling load to the return air. Treatment of such cases is discussed in Appendix F and an example is given in Chapter 8.

If the space airflow rate is different from the typical condition (i.e., about $1 \mathrm{cfm} / \mathrm{ft}^{2}$, Figure 6.1 can be used to estimate the lighting heat gain parameters. Design data shown in Figure 6.1 are only applicable for the recessed fluorescent luminaire without lens.

Although design data presented in Table 6.3 and Figure 6.1 can be used for a vented luminaire with side-slot returns, they are likely not applicable for a vented luminaire with lamp-compartment returns, because all heat convected in the vented luminaire with lamp-compartment returns would likely go directly to the ceiling plenum, resulting in a zero convective fraction and a much lower space fraction than that for a vented luminaire with side-slot returns. Therefore, the design data should only be used for a configuration where the conditioned air is returned through the ceiling grille or the luminaire side slots.

For other luminaire types not covered by ASHRAE RP-1282 (Fisher and Chantrasrisalai 2006), it may be necessary to estimate the heat gain for each component as a fraction of the total lighting heat gain by using judgment to estimate heat-to-space and heat-to-return percentages.

Because of the directional nature of downlight luminaires, a large portion of the shortwave radiation typically falls on the floor. When converting heat gains to cooling loads in the RTSM, solar radiant time factors (RTFs) may be more appropriate than nonsolar RTFs. (Solar RTFs are calculated assuming most of the solar radiation is intercepted by the floor; nonsolar RTFs assume a uniform distribution by area over all interior surfaces.) This effect may be significant for rooms where the lighting heat gain is high and for which the solar RTFs are significantly different from the nonsolar RTFs.

## Miscellaneous Equipment

Estimates of heat gain in this category tend to be even more subjective than for people and lights. However, considerable data are available that, when used judi-

| for radiative fraction if there are large holes in the |
| reflector of the luminaire. |

ciously, will yield reliable results. Careful evaluation of the operating schedule and the load factor for each piece of equipment is essential.

## Power

When equipment is operated by electric motor within a conditioned space, the heat equivalent is calculated as

AIR CONDITIONING COMPANY

$$
\begin{equation*}
q_{e m}=2545\left(P / E_{m}\right) F_{U M} F_{L M} \tag{6.2}
\end{equation*}
$$

where
$q_{e m}=$ heat equivalent of equipment operation, Btu/h
$P=$ motor power rating, hp
$E_{m}=$ motor efficiency, as decimal fraction $<1.0$
$F_{U M}=$ motor-use factor, 1.0 or decimal $<1.0$
$F_{L M}=$ motor-load factor, 1.0 or decimal $<1.0$
$2545=$ conversion factor, Btu/h•hp
The motor-use factor may be applied when motor use is known to be intermittent with significant nonuse during all hours of operation-for example, in the case of an overhead door operator. In these cases, the motor-use factor in any hour is equal to the fraction of time the motor is operated during the hour. For conventional applications, its value is 1.0 .

The motor-load factor is the fraction of the rated motor load delivered under the conditions of the cooling-load estimate. Heat output of a motor generally is proportional to the motor load, within the overload limits. Because of typically high no-load motor current, fixed losses, and other reasons, $F_{L M}$ is assumed to be unity, and no adjustment should be made for underloading or overloading unless the situation is fixed and can be accurately established and unless the reduced load efficiency data can be obtained from the motor manufacturer.

In Equation 6.2, both the motor and the driven equipment are assumed to be within the conditioned space. If the motor is outside the space or airstreams and the driven equipment is within the conditioned space, use

$$
\begin{equation*}
q_{e m}=2545(P) F_{U M} F_{L M} \tag{6.3}
\end{equation*}
$$

When the motor is inside the conditioned space or airstream but the driven machine is outside, use

$$
\begin{equation*}
q_{e m}=2545 P\left(\frac{1.0-E_{m}}{E_{m}}\right) F_{U M} F_{L M} \tag{6.4}
\end{equation*}
$$

Equation 6.4 also applies to a fan or pump in the conditioned space that exhausts air or pumps fluid outside that space.

Table 6.4 gives minimum efficiencies for typical electric motors of recent manufacture from ASHRAE/IES Standard 90.1-2010. If electric-motor heat gain is an appreciable portion of cooling load, the motor efficiency should be obtained from the manufacturer. Also, depending on design, the maximum efficiency might occur anywhere between $75 \%$ and $110 \%$ of full load. If underloaded or overloaded, the efficiency could vary from the manufacturer's listing.

Unless the manufacturer's technical literature indicates otherwise, the heat gain should be divided about $50 \%$ radiant and $50 \%$ convective for subsequent cooling load calculations.

## Food Preparation Appliances

In a cooling-load estimate, heat gain from all appliances-electric, gas, or steam-should be taken into account. The tremendous variety of appliances, applications, usage schedules, and installations makes estimates very subjective. To establish a heat gain value, actual input data values and various factors, efficiencies, or other judgmental modifiers are preferred. However, where specific rating data are not available, recommended heat gains tabulated in this chapter may be used as an alternative approach. In estimating the appliance load, probabilities of simultaneous use and operation of different appliances located in the same space must be considered.

In commercial kitchens, appliances are typically on and "up to temperature" for the entire day, though the actual amount of time that they are actually used for cooking is often less than $25 \%$ (Swierczyna et al. 2009.) Therefore, measured values of heat gains under idle conditions are often used for cooling load calculations. Recommended rates of heat gain corresponding to idle conditions are given in Tables 6.5a to 6.5a. For unhooded electric appliances, recommended rates of sensible radiant heat gain, sensible convective heat gain, and latent heat gain are given in the fourth, fifth, and sixth columns of Table 6.5 a . A usage factor, $F_{U}$, is also given-it is the ratio of the standby heat gain to the rated energy. The radiation factor $F_{R}$ given in the last column is the fraction of sensible heat gain that is radiant. These values have already been applied to the rates of heat gain that are given.

For hooded appliances, recommended heat gain rates are given in Tables 6.5b, 6.5 c , and 6.5 d . For hooded appliances, the convective and latent heat gains are assumed to be removed by the hood, so the remaining heat gain shown in the fourth column of each table is $100 \%$ radiant. As before, the usage factor and radiation factor have already been applied.

[^8]*Nominal efficiencies established in accordance with NEMA Standard MG1. Design A and Design B are National Electric Manufacturers Association (NEMA) design class designations for fixed-frequency small and medium AC squirrel-cage induction motors.

## Hospital and Laboratory Equipment

As with large kitchen installations, hospital and laboratory equipment is a major source of heat gain in conditioned spaces. Care must be taken in evaluating the probability and duration of simultaneous usage when many components are concentrated in one area, as in a laboratory, operating room, etc. The chapters related to health facilities and laboratories in the ASHRAE Handbook-HVAC Applications (2011) should be consulted for further information.

Tables 6.6 and 6.7 give recommended rates of heat gain for hospital equipment (Alereza and Breen 1984) and laboratory equipment (Hosni et al. 1999). These data are recommended where specific heat gain data and use schedules are not available.

As a general rule, for equipment that does not have significantly elevated surface temperatures, Hosni et al. (1999) recommend a radiative/convective split of $10 \% / 90 \%$ for fan-cooled equipment and $30 \% / 70 \%$ for non-fan-cooled equipment.

## Office Appliances

Computers, printers, copiers, and other office equipment can generate significant internal heat gains, and so it is important to adequately account for these heat gains when computing the cooling load. Past research has shown that nameplate data are not reliable indicators of actual heat gain, significantly overstating the heat gain. There are two approaches that may be taken to estimate office heat gains. The first approach involves estimating the heat gains on a piece-by-piece basis-a certain amount of heat gain is allocated to each appliance anticipated in

the space. To use this approach, Tables $6.8,6.9$, and 6.10 give recommended rates of heat gain for computers, printers, and miscellaneous office equipment (ASHRAE Handbook—Fundamentals [2013]). For larger spaces with many pieces of equipment, diversity should be considered. That is, not all of the equipment is likely to be on at any given time.

Diversity varies with occupancy-different types of businesses are likely to have different diversity factors. ASHRAE Research Project 1093 (Abushakra et al. 2004; Claridge et al. 2004) derived diversity profiles for a variety of office buildings.

A second approach simply estimates likely heat gain per unit area. Recommendations based on work by Wilkins and Hosni (2011) can be found in Table 6.11. The medium-load density should be sufficient for most standard office spaces. The heavy-load densities are likely to be conservative estimates even for densely populated spaces.

Like other internal heat gains, it is necessary to split the heat gain into radiant and convective components. Recommendations for specific office equipment are given in the footnotes of Tables 6.8 and 6.9. For other office equipment, Hosni et al. (1999) recommend a radiative/convective split of $10 \% / 90 \%$ for fan-cooled equipment and $30 \% / 70 \%$ for non-fan-cooled equipment.

Source: Hosni and Beck (2008).
 a conservative value of about 65 W may be used. Power consumption in sleep mode is negligible. Because of cooling fan, approximately $90 \%$ of load is by convection and $10 \%$ is by radiation. Actual power consumption is about 10 to $15 \%$ of nameplate value.
${ }^{\mathrm{c}}$ Flat-panel monitors have replaced cathode ray tube (CRT) monitors in many workplaces, providing better resolution and being much lighter. Power consumption depends on size and resolution, and ranges from about 20 W (for 15 in . size)

Source: Hosni and Beck (2008).
${ }^{\text {a }}$ Various laser printers commercially available and commonly used in personal offices were tested for power consumption in print mode, which varied from 75 to 140 W , depending on model, print capacity, and speed. Average power consumption of 110 W may be used. Split between convection and radiation is approximately $70 / 30 \%$.
${ }^{\mathrm{b}}$ Small multifunction (copy, scan, print) systems use about 15 to 30 W ; medium-sized ones use about 135 W . Power consumption in idle mode is negligible. Nameplate values do not represent actual power consumption and should not be used. Small, single-sheet scanners consume less than 20 W and do not contribute significantly to building cooling load.
${ }^{\text {c }}$ Power consumption for large copy machines in large offices and copy centers ranges from about 550 to 1100 W in copy mode. Consumption in idle mode varies from about 130 to 300 W . Count idle-mode power consumption as mostly convective in cooling load calculations.
${ }^{\mathrm{d}}$ Split between convective and radiant heat gain was not determined for these types of equipment.

Table 6.10 Recommended Heat Gain from Miscellaneous Office Equipment

| Equipment | Maximum Input Rating, W | Recommended Rate of Heat Gain, W |

Example 6.1 Heat Gain from Occupants

## Example 6.2 <br> Heat Gain from <br> Lights for Single Room

Determine the heat gain from eight people in a retail store. Divide the heat gain into components for cooling load calculation.

## Solution:

| Items | Table/Equation | Explanation |
| :---: | :---: | :---: |
| Heat gain per person | Table 6.1 | For degree of activity, use "Standing, light work; walking." Sensible and latent heat gains for the adjusted M/F group are: $q_{s}^{\prime}=250 \mathrm{Btu} / \mathrm{h}$ per person $q^{\prime}{ }_{l}=200 \mathrm{Btu} / \mathrm{h}$ per person |
| Total latent heat gain |  | $q_{l}=N q^{\prime}{ }_{l}=8 \cdot 200=1600 \mathrm{Btu} / \mathrm{h}$ |
| Total sensible heat gain |  | $q_{s}=\mathrm{Nq}_{s}=8 \cdot 250=2000 \mathrm{Btu} / \mathrm{h}$ |
| Radiant component of sensible heat gain |  | Assuming low air velocity, the radiant fraction is $58 \%$. $q_{r}=0.58 q_{s}=0.58 \cdot 2000=1160 \mathrm{Btu} / \mathrm{h}$ |
| Convective component of sensible heat gain |  | $\begin{gathered} \text { The convective fraction is } \\ 100 \%-58 \%=42 \% \\ q_{c}=0.42 q_{s}=0.42 \cdot 2000=840 \mathrm{Btu} / \mathrm{h} \\ \hline \end{gathered}$ |

[^9]AIR CONDITIONING COMPANY

| Item | Table/Equation | Explanation |
| :---: | :---: | :---: |
| Total installed wattage |  | $\begin{aligned} & \hline W=(4 \text { fixtures }) \cdot(3 \text { lamps/fixture }) \\ & \cdot(32 \mathrm{~W} / \text { lamp })=384 \mathrm{~W} \end{aligned}$ |
| Use factor, $F_{u l}$ |  | Assume $F_{u l}=1$ for single room |
| Special allowance factor, $F_{s a}$ |  | $F_{s a}=0.94$, determined from manufacturer's data |
| Heat gain | Eqn. 6.1 | $\begin{aligned} & q_{e l}=3.41 \mathrm{Btu} / \mathrm{h} / \mathrm{W} \cdot 384 \mathrm{~W} \\ & \cdot 1 \cdot 0.94=1231 \mathrm{Btu} / \mathrm{h} \end{aligned}$ |
| Heat gain to the space (sensible) | Table 6.3 | Space fraction $=45 \%$, taking a mean value of the range, as recommended in the text. $q=0.45 \cdot 1231 \mathrm{Btu} / \mathrm{h}=554 \mathrm{Btu} / \mathrm{h}$ |
| Radiant component of heat gain to the space | Table 6.3 | Again taking a mean value of the range, radiative fraction $=67 \%$ $q_{r}=554 \cdot 0.67=371 \mathrm{Btu} / \mathrm{h}$ |
| Convective component of heat gain to the space |  | Convective fraction is $100 \%-67 \%=$ 33\% $q_{c}=554 \cdot 0.33=183 \mathrm{Btu} / \mathrm{h}$ |
| Heat gain to return air |  | Plenum fraction is 1 -space fraction or $55 \%$. $q_{r a}=0.55 \cdot 1231 \mathrm{Btu} / \mathrm{h}=677 \mathrm{Btu} / \mathrm{h}$ <br> $q_{r a}$ is assumed to be all convective and an immediate load on the coil |

Example 6.3 Heat Gain from Motor-Driven Equipment

An air-conditioned machine shop has a motor-driven milling machine with a 3 hp motor estimated to be in operation $30 \%$ of the time. Estimate the heat gain and determine the various components for cooling load calculation.

## Solution:

| Item | Table/Equation | Explanation |
| :--- | :--- | :--- |
| Heat gain | Equation 6.2 | Both the motor and the driven <br> equipment are in the conditioned space |
| Motor use factor, $F_{U M}$ |  | From given information, $F_{u m}=0.3$ <br> The motor will usually be at partial load, <br> but the underloading is indeterminate; <br> therefore assume $F_{L M}=1$ |
| Motor load factor, $F_{L M}$ |  | Without additional information about <br> the specific motor, take the efficiency <br> from Table 6.4 |
| Motor efficiency, $E_{M}$ | Table 6.4 | $E_{M}=85.5 \%$ <br> $q_{e m}$ |
| Heat gain to the space | Equation 6.2 | $=2545 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{hp} \cdot(3 \mathrm{hp} / 0.855) \cdot 0.3 \cdot 1$ |
| (sensible) |  | $=2679 \mathrm{Btu} / \mathrm{h}$ |

\(\left.$$
\begin{array}{ll} & \begin{array}{l}\text { Without additional information, take } \\
\text { radiant/convective split as } 50 \% / 50 \%, \text { as } \\
\text { recommended in the text }\end{array} \\
\text { Radiant component of heat } \\
\text { gain to the space }\end{array}
$$ \quad \begin{array}{l}q_{r}=2679 \cdot 0.5 <br>
<br>

=1340 \mathrm{Btu} / \mathrm{h}\end{array}\right\}\)| $q_{c}=2679 \cdot 0.5$ |
| :--- |
| Convective component of |
| heat gain to the space |

Example 6.4 Heat Gain from Restaurant Equipment

Consider a flat, 3 ft electric griddle with rated heat input of $58,400 \mathrm{Btu} / \mathrm{h}$. While it will be hooded, consider both the hooded and unhooded cases. Estimate the heat gain and determine the various components for cooling load calculation.

## Solution:

| Item | Table / Equations | Explanation |
| :---: | :---: | :---: |
| Hooded case |  |  |
| Heat gain | Table 6.5b | With the hood in operation, there will only be sensible heat gain of $4500 \mathrm{Btu} / \mathrm{h}$, all of which is radiant. $q=4500 \mathrm{Btu} / \mathrm{h}$ |
| Radiant component, $q_{r}$ |  | For hooded appliances, all heat gain to the space is radiant. $q_{r}=4500 \mathrm{Btu} / \mathrm{h}$ |
| Convective component, $q_{c}$ |  | $q_{c}=0 \mathrm{Btu} / \mathrm{h}$ |
| Unhooded case |  |  |
| Heat gain | Table 6.5b | Without a hood in operation, the total heat gain is given in the $3^{\text {rd }}$ column of Table $\begin{gathered} 6.5 \mathrm{~b} \\ q=11,500 \mathrm{Btu} / \mathrm{h} \end{gathered}$ |
| Sensible heat gain, $q_{S}$ |  | The total sensible heat gain including convection may be determined by dividing the sensible radiant heat gain by the radiation factor $\begin{aligned} q_{S} & =4500 \mathrm{Btu} / \mathrm{h} / 0.39 \\ & =11,500 \mathrm{Btu} / \mathrm{h} \end{aligned}$ <br> (actually, the calculation gives 11,539 since the radiation factor is only given to two decimal places, but the sensible heat gain cannot be more than the total heat gain.) |
| Latent heat gain, $q_{L}$ |  | $q_{L}=q-q_{s}=0$ <br> How can the latent heat gain be zero? The heat gains in Table 6.5b are for standby conditions when no food will be on the griddle. In the event there is food on the griddle, we anticipate the hood being on. |
| Radiant component, $q_{r}$ of sensible heat gain |  | The radiant heat gain without the hood is the same as that with the hood. $q_{r}=4500 \mathrm{Btu} / \mathrm{h}$ |

# Fundamentals of the Radiant Time Series Method 

The radiant time series method (RTSM) is a simplified method for performing design cooling load calculations. It is derived from the heat balance method (HBM) and, when used within its limitations, gives results that are slightly conservative-that is, it overpredicts the cooling load by a small amount when compared to the HBM.
The RTSM was developed to be rigorous, without requiring iteration (as does the HBM) to determine conduction heat gains and cooling loads. The RTSM produces individual component heat gains and cooling loads that can be readily examined by the designer. In addition, the coefficients that are used to compute transient conduction heat gain and cooling loads have a physical meaning that can be understood by the user of the method. These characteristics allow the use of engineering judgment during the cooling load calculation process.

The RTSM is well suited for use in a spreadsheet. Although it is simple in concept, there are too many calculations required to be practical as a manual method. In the supporting files online (at www.ashrae.org/lcam) that accompany this manual are several different spreadsheets that implement the RTSM. In addition, each example in this chapter has an accompanying spreadsheet that implements the relevant part of the method.

### 7.1 Assumptions and Limitations of the RTSM

To develop the RTSM as a simplified replacement for the HBM, several key assumptions are required. These assumptions and the resulting limitations in the RTSM are as follows:

1. Calculation period-the RTSM assumes that the design day cooling load calculation is for a single day, with the previous days having the same conditions. In other words, any energy stored in the building overnight will be consistent with the previous days, having been identical in weather and internal heat gains. In practice, the HBM also uses this assumption, though the HBM also may be used with nonperiodic conditions. Accordingly, while the HBM may be adapted for use in multiday and annual energy calculation simulations, the RTSM is not appropriate for this use.
2. Exterior surface heat balance-the RTSM replaces the exterior surface heat balance by assuming that the exterior surface exchanges heat with an exterior boundary condition known as the sol-air temperature. The heat exchange is governed by the surface conductance, which is a combined radiative and convective coefficient. The HBM balances the heat flows (convective, radiative, and conductive) at the exterior surface and computes its temperature.
3. Interior surface heat balance and room air heat balance-the energy stored and later released by each surface dampens and delays the peak cooling load, so it is important to include in the analysis. The RTSM uses another approach that involves simplifying the radiation heat exchange and using data (radiant time factors) derived from the HBM to make a reasonably accurate estimate of the damping and delay. The HBM balances the heat flows (convective, radiative, and conductive) at the interior surface and all of the convective flows to and from the room air. This allows the HBM to account for all of the radiative exchanges and to keep track of the energy being stored and later released by each surface. The

RTSM simplification of the radiation exchange relies on two approximations: first, that the other surface temperatures can be reasonably approximated as being the same as the indoor air temperature, and second, that the fourth-order dependency on absolute surface temperatures can be approximated with a simple linear relationship. This, in turn, allows the radiation and convection to be combined and calculated with a single combined coefficient (called the surface conductance) multiplied by the difference between the interior surface temperature and the air temperature. Or, even more conveniently, they can be combined into a single resistance, becoming part of the total resistance of the wall.

The above assumptions allow the RTSM to proceed sequentially, without iteration. The latter two assumptions result in the RTSM not being able to give exactly the same answer as the HBM. For most cases, these differences are relatively unimportant, as the difference is generally a small percentage. One significant exception is the case of buildings with large amounts of low thermal resistance envelope area (e.g., single-pane glazing or possibly a fabric structure) (Rees et al. 1998). Similar to earlier simplified methods, the RTSM moderately overpredicts cooling loads in buildings with high fractions of single-pane exterior fenestration.

### 7.2 Overview of the RTSM

The RTSM has two basic steps: calculation of heat gains and calculation of cooling loads. In practice, additional steps are needed to prepare for calculation of the heat gains, and when breaking out all of the heat gain calculations by component type, the

Figure 7.1 Overview of the RTSM for a single zone.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Figure 8).

overall procedure looks slightly more complex, as shown in Figure 7.1. Furthermore, Figure 7.1 assumes initial data gathering has already been done-meaning that geometry, constructions, environmental design conditions, peak internal heat gains and schedules, etc. have already been determined.

### 7.3 Computation of Solar Irradiation and Sol-Air Temperatures

The computation of solar radiation incident on each surface is an important first step in computing cooling loads in any cooling load calculation procedure. (Solar irradiation is simply the radiation incident on a surface.) For the RTSM, it is also necessary to compute sol-air temperatures. The methodology for these computations and a spreadsheet implementation are described in Appendix D.

Using the spreadsheet 7-1-solar.xls (in the online supporting files accompanying this manual) with location, orientations, clearness number, etc. as inputs, the solar irradiation for vertical surfaces facing the cardinal and intercardinal directions are determined for each hour of the day and given in Table 7.1. With the additional information of the peak temperature, daily range, surface solar absorptivity, and surface conductance, the spreadsheet will also compute the sol-air temperatures, which are given in Table 7.2.

### 7.4 Computation of Conductive Heat Gains from Opaque Surfaces

Conductive heat gain is calculated for each wall and roof type with the use of a conduction time series (CTS). The 24 coefficients of the CTS are periodic response factors referred to as conduction time series factors (CTSFs). This formulation gives a time series solution to the transient, periodic, one-dimensional conductive heat transfer problem. For any hour, $\theta$, the conductive heat gain for the surface $q_{\theta}$ is given by the summation of the CTSFs multiplied by the $U A$ value multiplied by the temperature difference across the surface, as shown in Equation 7.1:

$$
\begin{equation*}
q_{\theta}=\sum_{j=0}^{23} c_{j} U A\left(t_{e, \theta-j \delta}-t_{r c}\right) \tag{7.1}
\end{equation*}
$$

or

$$
\begin{gather*}
q_{\theta}=c_{0} U A\left(t_{e, \theta}-t_{r c}\right)+c_{1} U A\left(t_{e, \theta-\delta}-t_{r c}\right)+c_{2} U A\left(t_{e, \theta-2 \delta}-t_{r c}\right)  \tag{7.2}\\
+\ldots+c_{23} U A\left(t_{e, \theta-23 \delta}-t_{r c}\right)
\end{gather*}
$$

where
$q_{\theta}=$ hourly conductive heat gain, Btu/h, for the surface
$U=$ overall heat transfer coefficient for the surface, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$A=$ surface area, $\mathrm{ft}^{2}$
$c_{j}=j^{\text {th }}$ conduction time series factor
$t_{e, \theta-j \delta}=$ sol-air temperature, ${ }^{\circ} \mathrm{F}, j$ hours ago
$t_{r c}=$ presumed constant room air temperature, ${ }^{\circ} \mathrm{F}$
$\theta=$ the current hour
$\delta \quad=$ the time step (one hour)
Note that the quantity $U A\left(t_{e, \theta-j \delta}-t_{r c}\right)$ would be the heat transfer at each hour if steady-state conditions prevailed. The conduction time factors may be thought of as an adjustment to the steady-state heat transfer calculation, telling us how much heat that was previously stored in the wall or roof is released this hour. Figure 7.2 illustrates conduction time series for three different walls ranging from light to very heavy. As can be seen, the CTSFs for the very light wall are large for the first few hours and nearly zero for the remaining hours-relatively little heat is stored in this lightweight wall. On the other hand, the heavier walls have smaller values of CTSFs early on but they remain nonzero for many hours, indicating the long time delay inherent in the heavier walls.

CTSFs may be obtained in several different ways. They are given for sample walls and roofs in Tables 7.3a, 7.3b, and 7.4, they may be determined with the spreadsheet in the online supporting files that accompany this manual and that contain the contents of Tables 7.3 and 7.4 (7-3_tabulated_CTSF.xls), or they may be determined with the spreadsheet interface to a program implemented in Visual

## Wall Number Descriptions

Spandrel glass, R-10 insulation board, gyp board Metal wall panel, R-10 insulation board, gyp board 1 in . stone, R-10 insulation board, gyp board Metal wall panel, sheathing, R-11 batt insulation, gyp board 1 in . stone, sheathing, R-11 batt insulation, gyp board Wood siding, sheathing, R-11 batt insulation, $1 / 2 \mathrm{in}$. wood 1 in . stucco, sheathing, R-11 batt insulation, gyp board EIFS finish, R-5 insulation board, sheathing, gyp board EIFS finish, R- 5 insulation board, sheathing, R-11 batt insulation, gyp board
EIFS finish, R- 5 insulation board, sheathing, 8 in. LW CMU, gyp board

Brick, R-5 insulation board, sheathing, gyp board
Brick, sheathing, R-11 batt insulation, gyp board
Brick, R-5 insulation board, sheathing, R-11 batt insulation, gyp board
Brick, R-5 insulation board, 8 in. LW CMU
Brick, 8 in. LW CMU, R-11 batt insulation, gyp board
Brick, R-5 insulation board, 8 in. HW CMU, gyp board Brick, R-5 insulation board, brick
Brick, R-5 insulation board, 8 in. LW concrete, gyp board Brick, R-5 insulation board, 12 in. HW concrete, gyp board Brick, 8 in. HW concrete, R-11 batt insulation, gyp board

Basic for Applications (VBA) (7-4_generate_CTSF.xls). Thermal properties of the materials used for the walls and roofs in Tables 7.3a, 7.3b, and 7.4 are given in Table 7.5.

In the case of using the tables, engineering judgment is required to select a similar wall type. In questionable cases, particularly where the conduction heat gain may form a significant part of the cooling load, it may be desirable to use the 7-4_generate_CTSF.xls spreadsheet, which allows the user to specify the wall or roof in a layer-by-layer fashion. For walls or roofs with studs or other thermal bridges, consult Appendix E for the appropriate methodology.

### 7.5 Computation of Fenestration Heat Gains

Fenestration (e.g., windows and skylights) allow heat gains via transmitted solar radiation, absorbed solar radiation, and conduction. While the inward-flowing fraction of the absorbed solar radiation and the conduction are interrelated, a reasonable approximation is to calculate them separately.

A problem in computing fenestration heat gains is the lack of data generally available in practice. Whereas Chapter 15 of ASHRAE Handbook-Fundamentals (2013) gives angle-dependent values of solar heat gain coefficients (SHGCs), transmittances, absorptances, etc., in many situations it will be difficult or impossible to choose the correct window from the tables in Chapter 15.

Understanding this, the method presented here (Barnaby et al. 2004) incorporates some approximations that allow it to rely solely on the data that are actually provided by window manufacturers, including the following:

- Number of layers-is the window single-pane, double-pane, or triple-pane?

- Some description of the glass type-coloration and whether or not it has a low-e coating, for example. This information is often vague when compared to the tabulated layer description.
- U-factor (NFRC 2004a).
- SHGCs at normal-incidence-angle SHGC (NFRC 2004b).
- Visual transmittance (NFRC 2004b).

Using the manufacturer's information, the engineer chooses a window type from the tabulated set of windows in Tables 7.9 or 3.8. (Table 7.9 is a subset of Table 3.8.)

# Table 7.5 Thermal Properties and Code Numbers of Layers Used in Wall and Roof Descriptions for Tables 7.3a, 7.3b, and 7.4 

(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Table 18)

Example 7.1 Conduction Heat Gain

Consider a $100 \mathrm{ft}^{2}$ SE-facing wall in Atlanta, Georgia, on July 21. From the materials list in Table 7.5, the material layers, from outside to inside, are given as M01, F04, I01, M03, I01, and G01. (To this, outside and inside surface resistances will be added.) The outer layer of brick is red and the solar absorptivity may be taken from Table 3.3b as 0.63 . Using the ASHRAE July $5 \%$ design weather data, find the conduction heat gain for the wall at 5:00 p.m., EDST. The indoor air temperature is $75^{\circ} \mathrm{F}$.

## Solution:

Weather data for Atlanta are found in Table 4.1. The peak daily temperature is $91.9^{\circ} \mathrm{F}$, and the mean coincident dry-bulb range for July is $20.5^{\circ} \mathrm{F}$. The wind speed is not known exactly, but the mean coincident wind speed for the annual $0.4 \%$ design condition is 8.7 mph . Taking this as the wind speed, the actual surface conductance can be interpolated from Table 3.4 as $4.3 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$ and the resulting resistance as $0.23 \mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$. Alternatively, the standard value for summer conditions, equivalent to Layer F01 in Table $7.5\left(0.25 \mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}\right)$, may be used with little loss of accuracy. The interior surface resistance may be taken from Table 3.4 as $0.68 \mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$; this is equivalent to Layer F02 in Table 7.5. Using F01 and F02 for the exterior and interior surface conductances, the wall may be summarized as shown in Table 7.6, with a total resistance of $15.34 \mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$ and a U-factor of $0.065 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$.

In reviewing Tables 7.3a and 7.3b, it is clear that this wall (mentioned in Table 7.6) is similar to wall 14 except it has an extra layer of R-5 insulation board covered by $5 / 8 \mathrm{in}$. gypsum added to the inside. It is also similar to wall 15 , except this wall has an extra layer of insulation board between the brick and concrete block and R-5 insulation board instead of the R-11 batt between the concrete block and the gypsum layer. A challenge of using the tables in practice is matching the actual wall construction to a wall with a similar thermal response. For this example, conduction time factors given in Table 7.3a for both wall 14 and wall 15 will be used. For comparison purposes, conduction time factors for the actual wall will also be computed using a spreadsheet, Example 7.1 Compute CTSFxIs, which is available online in the supporting files that accompany this manual. All three sets of conduction time factors are shown in Table 7.7.

Table 7.6 Example Wall

| Layer Code | Layer Description | Thickness, in. | Conductivity, Btu-in./h-ft ${ }^{2}{ }^{\circ} \mathrm{F}$ | Density, $\mathrm{lb}_{\mathrm{m}} / \mathrm{ft}^{3}$ | Specific Heat, $\mathbf{B t u} / \mathbf{b o}_{\mathrm{m}}{ }^{\circ} \mathbf{F}$ | Resistance, $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot \mathrm{~F} / \mathrm{Btu}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| F01 | Outside surface resistance |  |  |  |  | 0.25 |
| M01 | 4 in. brick | 4.0 | 6.20 | 120.00 | 0.19 | 0.65 |
| F04 | Wall air space resistance | 0.0 | 0.00 | 0.000 | 0.00 | 0.87 |
| 101 | $\mathrm{R}-5,1 \mathrm{in}$. insulation board | 1.0 | 0.20 | 2.7 | 0.29 | 5.00 |
| M03 | 8 in. LW concrete block | 8.0 | 3.44 | 29.00 | 0.21 | 2.33 |
| 101 | R-5, 1 in. insulation board | 1.0 | 0.20 | 2.7 | 0.29 | 5.00 |
| G01 | $5 / 8$ in. gypsum board | 0.625 | 1.11 | 50.00 | 0.26 | 0.56 |
| F02 | Inside vertical surface resistance |  |  |  |  | 0.68 |
| Sum of the Resistances |  |  |  |  |  | 15.34 |

Total incident solar radiation, outdoor air temperatures, and sol-air temperatures for each hour are given in Table 7.8. The conduction heat gain, using the tabulated CTSFs for wall 14 with Equation 7.1, is:

$$
\begin{aligned}
& 0.01(0.065)(100)(97.7-75.0)+0.01(0.065)(100)(99.1-75.0) \\
&+0.02(0.065)(100)(99.5-75.0)+0.05(0.065)(100)(103.6-75.0) \\
& q_{17}=+0.08(0.065)(100)(109.2-75.0)+0.09(0.065)(100)(111.7-75.0) \\
& \vdots \\
&+0.01(0.065)(100)(91.6-75.0)+0.0(0.065)(100)(94.8-75.0) \\
& q_{17}= 109.5 \mathrm{Btu} / \mathrm{h}
\end{aligned}
$$

The same computation, using the tabulated CTSFs for wall 15 and the computed CTSFs, give heat gains of 90.1 and $83.1 \mathrm{Btu} / \mathrm{h}$, respectively. Using the CTSFs for wall 14 overpredicts the conduction heat gain at $5: 00 \mathrm{p} . \mathrm{m}$. by $32 \%$, while the CTSFs for wall 15 give a comparatively close result. (In both cases, the comparison is to the value determined with the computed CTSFs, which will be correct to the degree that the sol-air temperatures and thermal properties of the wall layers are correct.) The heat gains vary more significantly for some other hours. If the computation is repeated for every hour of the day using the spreadsheet Example 7.1 Conduction.xls, the resulting heat gains are shown in Table 7.8 and plotted in Figure 7.3. Note that, while the solar irradiation and outdoor air temperature follow Tables 7.1 and 7.2 exactly, the sol-air temperatures are lower than those shown in Table 7.2. This is due to the difference in solar absorptivity and exterior surface conductance for this wall. (The ratio $\alpha / h_{o}$ is $0.63 / 4.0=0.16$ for this example; Table 7.2 was developed for a wall with $\alpha / h_{o}=0.9 / 3.0=0.3$.) $\alpha / h_{o} \alpha / h_{o}$

The differences in the results illustrate the importance of choosing the correct wall type. The conduction heat gains can be quite sensitive to the wall type. In many cases,

AIR CONDITIONING COMPANY
the conduction heat gain will be a small part of the overall cooling load, and a rough approximation may have little effect on the overall cooling load, particularly for wellinsulated buildings with significant amounts of fenestration and/or internal heat gains. However, for buildings where conduction heat gain through the walls and/or roof forms a significant part of the cooling load, it is best to calculate CTSFs for the actual construction rather than relying on tabulated values for the closest construction.

Figure 7.3 Hourly conduction heat gains using three different sets of CTSFs.

AIR CONDITIONING COMPANY

The designer should look for a window that has a matching number of layers, the closest possible match to the tabulated values of normal SHGC and visual transmittance $T_{v}$, and a reasonably close match to the description of the layers, if possible.

Once the best match has been found, the angle-dependent SHGCs are determined by multiplying the manufacturer-specified SHGC by the angle correction factors in Tables 7.9 or 3.8. A SHGC value for any incidence angle can then be determined with linear interpolation. These values, along with the manufacturer-specified U-factor, are used as demonstrated in Example 7.2 to compute the heat gains due to fenestration.

Conduction heat gain is computed separately from the transmitted and absorbed solar heat gain. Because the thermal mass of the glass is very low, the conduction is approximately steady state. Accordingly, for each hour, the conduction heat gain may be calculated as

$$
\begin{equation*}
q_{\theta}=U A\left(t_{o, \theta}-t_{r c}\right) \tag{7.3}
\end{equation*}
$$

where
$q_{\theta}=$ hourly conductive heat gain, Btu/h, for the window
$U=$ overall heat transfer coefficient for the window, Btu/h $\cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$ as specified by the window manufacturer
$A=$ window area-including frame, $\mathrm{ft}^{2}$

Table 7.9 Angle Correction Factors for SHGC

| ID | \# of layers | SHGC Angle Correction Factors and Diffuse Correction Factor |  |  |  |  |  |  | Description |  |  |

Note: See Table 3.8 for a more complete list.
$t_{o,} \theta=$ outdoor air temperature, ${ }^{\circ} \mathrm{F}$
$t_{r c}=$ presumed constant room air temperature, ${ }^{\circ} \mathrm{F}$
$\theta=$ the current hour
Transmitted and absorbed solar heat gains are calculated for each hour with a step-by-step procedure, as follows:

1. Compute incident angle, surface azimuth angle, incident direct (beam) irradiation, and diffuse irradiation on window, as described in Appendix D.
2. If exterior shading exists, determine sunlit area and shaded area, as described in Appendix D.
3. With no interior shading, the beam, diffuse, and total transmitted and absorbed solar heat gains are given by

$$
\begin{gather*}
q_{S H G, D}=E_{D} A_{\text {sunlit }} \mathrm{SHGC}(\theta)  \tag{7.4a}\\
q_{S H G, d}=\left(E_{d V}+E_{r}\right) A \cdot \mathrm{SHGC}_{\text {diffuse }}  \tag{7.4b}\\
q_{S H G}=q_{S H G, D}+q_{S H G, d} \tag{7.4c}
\end{gather*}
$$

where

| $q_{S H G, D}$ | $=$ direct (beam) solar heat gain, Btu/h•ft ${ }^{2}$ |
| :---: | :---: |
| $q_{S H G, d}$ | $=$ diffuse solar heat gain, Btu/h.ft ${ }^{2}$ |
| $q_{S H G}$ | $=$ total solar heat gain, Btu/h.ft ${ }^{2}$ |
| $E_{D}$ | $=$ incident direct (beam) irradiation, Btu/h.ft ${ }^{2}$ |
| $E_{d V}$ | $=$ incident diffuse irradiation from sky on a vertical surface, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$ |
| $E_{r}$ | $=$ incident diffuse reflected irradiation, Btu/h•ft ${ }^{2}$ |
| SHGC ( $\theta$ ) | $=$ angle-dependent SHGC determined from manufacturer's normal SHGC corrected by correction factors in Table 7.9 or 3.8 |
| $\mathrm{SHGC}_{\text {diffuse }}$ | $=$ the SHGC for diffuse irradiation, determined by multiplying the manufacturer's normal SHGC by the diffuse correction factor in Table 7.9 or 3.8 |
| $\mathrm{IAC}_{\text {diff }}$ | $=$ interior attenuation coefficient applying to diffuse irradiation on a specific window/shade combination, as tabulated in Tables 3.9a-3.9g |
| $A_{\text {sunlit }}$ | $=$ the unshaded area of the window, $\mathrm{ft}^{2}$ |
|  | $=$ the total area of the window, including the frame, $\mathrm{ft}^{2}$ |

If there is no interior shading, the window heat gain calculation is complete.
4. With interior shading, such as Venetian blinds or draperies, the effects on solar heat gain may be estimated with interior attenuation coefficients (IACs), which are tabulated in Tables 3.9 a through 3.9 g . Use of the tables to obtain IACs is described in Chapter 3. The direct and diffuse solar heat gains determined with Equations 7.4a through 7.4 c are multiplied by angle-dependent and diffuse IACs to determine the solar heat gain with the interior shading layer. For the direct (beam) solar heat gain, the IAC depends on the profile angle as given by Equation 3.6. Then, the total solar heat gain is given by

$$
\begin{gather*}
q_{\mathrm{SHG}}=E_{D} A_{\text {sunlit }} \operatorname{SHGC}(\theta) \mathrm{IAC}(\theta, \Omega)+  \tag{7.5}\\
\quad\left(E_{d V}+E_{r}\right) A \cdot \operatorname{SHGC}_{\text {diffuse }} \mathrm{IAC}_{\text {diff }}
\end{gather*}
$$

The first line of Equation 7.5 is the direct part of the solar heat gain; the second line represents the diffuse portion.

## Load Calculation Applications Manual (I-P), Second Edition

Example 7.2 Solar Heat Gain Calculation

Compute the solar heat gain for a window facing $30^{\circ}$ east of south in Atlanta, Georgia, at $33.64^{\circ} \mathrm{N}$ latitude and $84.43^{\circ} \mathrm{W}$ longitude on July 21 at $12: 00$ p.m. EDST. The room temperature is $75^{\circ} \mathrm{F}$. The window is 4 ft high and 4 ft wide; the exterior surface is flush with the outside of the building wall, and it has a horizontal shading surface at the top of the window that extends out from the building 1 ft . The window manufacturer gives the following information:

- Double-pane window with a low-e coating and a soft gray tint. Neither the location of the coating nor the degree of window tinting is specified.
- The U-factor is given as $0.32 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$.
- The normal SHGC is given as 0.26 .
- The visual transmittance is given as 0.32 .

Compute the solar heat gain for the case where the window has no internal shading and for the case where it has light-colored interior miniblinds.

Solution: First, the incident angles, shading, and incident irradiation are determined using the procedures described in Appendix D. Then, the window properties, including appropriate values of SHGC, are determined. Lastly, the solar heat gains with and without internal shading are calculated.

Conduction Heat Gain. The U-factor is given by the manufacturer as $0.32 \mathrm{Btu} /$ $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$. The area of the window is $16 \mathrm{ft}^{2}$. The air temperature at noon is $85.0^{\circ} \mathrm{F}$. From Equation 7.3, the conduction heat gain at noon is

$$
q_{\text {cond }, 12}=0.32 \cdot(16) \cdot(85.0-75.0)=51.2 \mathrm{Btu} / \mathrm{h}
$$

Incident Angle Calculation. The local standard time for Atlanta in the summer is one hour before the local daylight savings time:

$$
12: 00-1: 00=11: 00
$$

The equation of time for July from Table D. 1 in Appendix D is -6.20 min. From Equation D.2, the local solar time to the nearest minute then becomes

$$
11: 00-6.2 / 60+(75-84.43) / 15=10.268, \text { or } 10: 16 \text { a.m. }
$$

The hour angle (Equation D.3) 1 hour and 44 minutes before solar noon is equal to $-26.0^{\circ}$. The declination for July, from Table D.1, is $20.6^{\circ}$. Here, we use the value calculated with Equation D.7, $20.64^{\circ}$. The solar altitude angle is given by Equation D.4:

$$
\begin{gathered}
\beta=\sin ^{-1}\left[\cos \left(33.64^{\circ}\right) \cos \left(-26.0^{\circ}\right) \cos \left(20.64^{\circ}\right)\right. \\
\left.+\sin \left(33.64^{\circ}\right) \sin \left(20.64^{\circ}\right)\right]=63.56^{\circ}
\end{gathered}
$$

The solar azimuth angle is calculated from Equation D.5b:

$$
\begin{gathered}
\phi=\cos ^{-1}\left(\frac{\sin \left(20.64^{\circ}\right) \cos \left(33.64^{\circ}\right)-\cos \left(20.64^{\circ}\right) \sin \left(33.64^{\circ}\right) \cos \left(-26.0^{\circ}\right)}{\cos \left(63.56^{\circ}\right)}\right) \\
=112.79^{\circ}
\end{gathered}
$$

The surface solar azimuth angle is calculated using Equation D.6:

$$
\gamma=\left|112.79^{\circ}-150^{\circ}\right|=37.21^{\circ}
$$

```
AIR CONDITIONING COMPANY
```

The angle of incidence can then be calculated using Equation D.7:

$$
\begin{aligned}
\theta= & \cos ^{-1}\left[\cos \left(63.56^{\circ}\right) \cos \left(37.21^{\circ}\right) \sin \left(90^{\circ}\right)\right. \\
& \left.+\sin \left(63.56^{\circ}\right) \cos \left(90^{\circ}\right)\right]=69.23^{\circ}
\end{aligned}
$$

Solar Radiation Calculation. The ASHRAE clear-sky model (covered in Section D. 2 of Appendix D) is used to calculate the beam and diffuse irradiation. Equation D. 15 is used to determine the extraterrestrial solar irradiation, $E_{o}$. The relative air mass, $m$, is calculated with Equation D.16. The beam and diffuse optical depths ( $\tau_{b}$ and $\tau_{d}$ ) are taken from the July column of rows 38 and 39 of Table 4.1. Then the air mass exponents, $a b$ and $a d$, are calculated with Equations D. 17 and D.18. The normal beam irradiation $E_{b}$ is then calculated with Equation D.19. The direct (beam) radiation incident on the wall $E_{b, t}$ is then calculated with Equation D.21:

$$
\begin{gathered}
E_{0}=433.3 \cdot\left\{1+0.033 \cos \left[360^{\circ} \frac{(202-3)}{365}\right]\right\}=419.6 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \\
m=\frac{1}{\sin 63.56^{\circ}+0.50572 \cdot 6.07995+63.56^{\circ}-1.6364}=1.116 \\
a b=1.454-0.406 \cdot 0.440-0.268 \cdot 2.202+0.021 \cdot 0.440 \cdot 2.202=0.706 \\
a d=0.507+0.205 \cdot 0.440-0.080 \cdot 2.202-0.190 \cdot 0.440 \cdot 2.202=0.237 \\
E_{b}=419.6 \cdot e^{\left[-0.440 \times\left(1.116^{0.706}\right)\right]}=260.8 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \\
E_{t, b}=260.8 \cdot \cos \left(69.23^{\circ}\right)=92.5 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}
\end{gathered}
$$

The diffuse radiation on a horizontal surface is given by Equation D.20, and the resulting diffuse radiation on the vertical wall is given by Equations D. 22 and D.23:

$$
\begin{gathered}
E_{d}=419.6 \cdot e^{\left[-2.202 \cdot\left(1.116^{0.237}\right)\right]}=43.8 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \\
Y=0.55+0.437 \cos \left(69.23^{\circ}\right)+0.313 \cos ^{2}\left(69.23^{\circ}\right)=0.744 \\
E_{d, t}=0.744 \cdot 43.8=32.6 \quad \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}
\end{gathered}
$$

The reflected radiation on the window is given by Equation D.26:

$$
E_{r}=\left(260.8 \cdot \sin 63.56^{\circ}+43.8\right) \cdot 0.2 \cdot 0.5=27.7 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}
$$

External Shading Calculation. The window has a horizontal overhang only. The profile angle for the horizontal projection is given by Equation D.28:

$$
\begin{aligned}
\tan \Omega & =\frac{\tan \beta}{\cos \gamma}=\frac{\tan \left(63.56^{\circ}\right)}{\cos \left(37.21^{\circ}\right)}=2.525 \\
\Omega & =\tan ^{-1}\left(2.525^{\circ}\right)=68.39^{\circ}
\end{aligned}
$$

The height of the horizontal overhang projection is given by Equation D.29:

$$
S_{H}=1.0 \cdot \tan \left(68.39^{\circ}\right)=2.52 \mathrm{ft}
$$

## Load Calculation Applications Manual (I-P), Second Edition

The window sunlit and shaded areas from Equations D. 31 and D.32, respectively, are given by

$$
\begin{gathered}
A_{S L}=[4-(0-0)] \cdot[4-(2.52-0)]=5.90 \mathrm{ft}^{2} \\
A_{S H}=16.0-5.90=10.10 \mathrm{ft}^{2}
\end{gathered}
$$

The horizontal projection is 2.52 ft , so the window will be partially shaded, with $36.9 \%$ (the lower 1.48 ft ) exposed to direct and diffuse radiation covers and $63.1 \%$ (the upper 2.52 ft ) exposed only to diffuse solar radiation.

Solar Heat Gain Calculation. The SHGC angle correction factor is taken from Table 7.9 or 3.8. The most similar window in terms of number of panes, description, normal SHGC, and visual transmittance is window 25E. The angledependent SHGC is then determined as the product of the normal SHGC (0.24) and the SHGC angle correction factor 0.680 determined by interpolation between angle $60^{\circ}$ and $70^{\circ}$ in row 25E of Table 7.9. The diffuse SHGC is similarly obtained by multiplying the normal SHGC by the diffuse angle correction factor taken from row 25 E of Table 7.9. The SHGCs are then

$$
\begin{aligned}
\operatorname{SHGC}\left(69.23^{\circ}\right) & =0.24 \cdot 0.680=0.163 \\
\text { SHGC }_{\text {diffuse }} & =0.24 \cdot 0.875=0.210
\end{aligned}
$$

If the window has no internal shading, the beam, diffuse, and total solar heat gains can be calculated directly using Equation 7.4:

$$
\begin{gathered}
q_{S H G, D, 12}=92.5 \cdot 5.90 \cdot 0.163=89.0 \mathrm{Btu} / \mathrm{h} \\
q_{S H G, d, 12}=(32.6+27.7) \cdot 16 \cdot 0.210=202.7 \mathrm{Btu} / \mathrm{h} \\
q_{S H G, 12}=89.0+202.7=291.7 \mathrm{Btu} / \mathrm{h}
\end{gathered}
$$

To determine the solar heat gains with the light-colored miniblind, it is necessary to look up the IAC values. Here, we interpret light-colored miniblinds to have a reflectance of 0.8 and we choose the blinds to be oriented at a $45^{\circ}$ angle. From Table 3.9 e , in the glazing type 25 e column, $\mathrm{IAC}_{0}=0.84, \mathrm{IAC}_{60}=0.79$, and $\mathrm{IAC}_{\text {diff }}$ $=0.87$. The profile angle is the same as computed for the external shading above, $68.4^{\circ}$. Using Equation 3.6, the $\operatorname{IAC}(\theta, \Omega)=0.79$. The solar heat gains corrected for the light-colored miniblind interior shading element become

$$
\begin{gathered}
q_{S H G, 12}=92.5 \cdot 5.9 \cdot 0.163 \cdot 0.79+ \\
(32.6+27.7) \cdot 16 \cdot 0.21 \cdot 0.87=246.5 \mathrm{Btu} / \mathrm{h}
\end{gathered}
$$

The total heat gain for the window is obtained by adding the solar heat gain and the conduction heat gain:

$$
\begin{gathered}
q_{12}=q_{\text {cond }, 12}+q_{S H G, 12} \\
q_{12}=51.2+246.5=297.7 \mathrm{Btu} / \mathrm{h}
\end{gathered}
$$

Example 7.2 Window.xls, included on the online supporting files that accompany this manual, demonstrates this computation for all hours of the day.

AIR CONDITIONING COMPANY

### 7.6 Computation of Internal and Infiltration Heat Gains

As with any load calculation procedure, internal heat gains due to occupants, lighting, and equipment must be estimated for each hour. Chapter 6 covers procedures and data for estimating internal heat gains.

Likewise, heat gains due to infiltration must also be estimated. Procedures and data for estimating infiltration flow rates are given in Chapter 5.

### 7.7 Splitting Heat Gains into Radiative and Convective Portions

The instantaneous cooling load is defined as the rate at which heat energy is convected to the zone air at a given point in time. The computation of convective heat gains is complicated by the radiant exchange between surfaces, furniture, partitions, and other mass in the zone. Radiative heat transfer introduces a time dependency into the process that is not easily quantified. Heat balance procedures calculate the radiant exchange between surfaces based on their surface temperatures and emissivities but typically rely on estimated radiative/convective splits to determine the contribution of internal heat sinks and sources to the radiant exchange. The radiant time series procedure simplifies the heat balance procedure by splitting all heat gains into radiative and convective portions instead of simultaneously solving for the instantaneous convection and radiative heat transfer from each surface. Table 7.10 contains recommendations for splitting each of the heat gain components.

According to the radiant time series procedure, once each heat gain is split into radiative and convective portions, the heat gains can be converted to cooling loads. The radiative portion is absorbed by the thermal mass in the zone and then convected into the space. This process creates a time lag and dampening effect. The convective portion, on the other hand, is assumed to instantly become cooling load and, therefore, only needs to be summed to find its contribution to the hourly cooling load. The method for converting the radiative portion to cooling loads is discussed in the next sections.

### 7.8 Conversion of Radiative Heat Gains into Cooling Loads

The RTSM converts the radiant portion of hourly heat gains to hourly cooling loads using radiant time factors (RTFs). Radiant time series calculate the cooling load for the current hour on the basis of current and past heat gains. The radiant time series for a particular zone gives the time-dependent response of the zone to a single, steady, periodic pulse of radiant energy. The series shows the portion of the radiant pulse that is convected to the zone air for each hour. Thus, $r_{0}$ represents the fraction of the radiant pulse convected to the zone air in the current hour, $r_{1}$ in the previous hour, and so on. The radiant time series thus generated is used to convert the radiant portion of hourly heat gains to hourly cooling loads according to Equation 7.6:

$$
\begin{equation*}
Q_{\theta}=r_{0} q_{\theta}+r_{1} q_{\theta-\delta}+r_{2} q_{\theta-2 \delta}+r_{3} q_{\theta-3 \delta}+\ldots+r_{23} q_{\theta-23 \delta} \tag{7.6}
\end{equation*}
$$

where
$Q_{\theta} \quad=$ cooling load $(Q)$ for the current hour $\theta$
$q_{\theta} \quad=$ heat gain for the current hour
$q_{\theta-n \delta} \quad=$ heat gain $n$ hours ago
$r_{0}, r_{1}$, etc. $=$ RTFs
RTFs are unique to each zone and depend on the zone geometry, envelope constructions, internal partitions and thermal mass, etc. Furthermore, they also depend on the distribution of the radiant energy entering the zone. In many cases, beam solar
radiation transmitted through windows will primarily strike the floor. Radiation emitted by occupants, equipment, etc. will tend to be distributed to all surfaces in the zone. In the common case where the floor is thermally massive while the walls and ceiling are lightweight, this can lead to a significant difference in thermal response between solar radiation and nonsolar radiation. As a result, two different sets of RTFs are uti-lized-one set that applies to transmitted solar radiation and another set that applies to radiation from internal heat gains and building envelope surfaces. The second set is labeled nonsolar radiation.

A representative set of RTFs for a range of zones is given in Tables 7.11 and 7.12. The test zone geometry and construction details used to generate the RTFs in Tables 7.11 and 7.12 are described in Table 7.13. It should be noted that the test zone has a single external wall, hence the percentage glass figures given in Tables 7.11 and 7.12 are based on a percentage of the single external wall.

To use these tables, the zone that most closely matches the room must be selected. In cases where the zone does not clearly match any of the sample zones, the engineer may wish to calculate RTFs for the specific zone in question. Spreadsheet tools for doing this are the files 7-6 RTF_tabulated.xls (a standalone version) and Example 7.3 RTF Generation.xls, both in the online supporting files accompanying this manual. Use of the second spreadsheet is demonstrated in Example 7.3.

## Table 7.10 Recommended Radiative/Convective Splits for Internal Heat Gains

(Source: Nigusse 2007)

| Heat Gain Type | Recommended Radiative Fraction | Recommended Convective Fraction | Comments |
| :---: | :---: | :---: | :---: |
| Occupants-typical office conditions | 0.6 | 0.4 | See Table 6.1 for other conditions. |
| Equipment | 0.1-0.8 | 0.9-0.2 | See Chapter 6 for detailed |
| Office equipment with fan | 0.10 | 0.9 | coverage of equipment heat gain and recommended radiative/ convective splits for motors, |
| Office equipment without fan | 0.3 | 0.7 | cooking appliances, laboratory equipment, medical equipment, office equipment, etc. |
| Lighting |  |  | Varies-see Table 6.3. |
| Conduction heat gain through walls and floors | 0.46 | 0.54 |  |
| Conduction heat gain through roofs | 0.60 | 0.40 |  |
| Conduction heat gain | $\begin{gathered} 0.33 \\ (\mathrm{SHGC}>0.5) \end{gathered}$ | $\begin{gathered} 0.67 \\ (\mathrm{SHGC}>0.5) \end{gathered}$ |  |
| through windows | $\begin{gathered} 0.46 \\ (\mathrm{SHGC} \leq 0.5) \end{gathered}$ | $\begin{gathered} 0.54 \\ (\mathrm{SHGC} \leq 0.5) \end{gathered}$ |  |
| Solar heat gain through fenestration w/o interior shading | 1.0 | 0.0 |  |
| Solar heat gain through fenestration w/interior shading |  |  | Varies; see Tables 3.9a to 3.9e |
| Infiltration | 0.0 | 1.0 |  |

When considering how closely the actual zone should match a zone in Tables 7.11 and 7.12 , or when considering how to specify a zone with the RTF generation tool, some engineering judgment is required. The primary purpose of the RTFs is to quantify how fast the zone responds to heat gains. Consider Figure 7.4, where the RTFs applying to transmitted solar heat gain are plotted for three sample zones-a lightweight zone without carpeting, a heavyweight zone with carpeting, and a heavyweight zone without carpeting-all with $10 \%$ glazing on one wall. The curves represent the response of the zone: the higher the value at the beginning, the faster the zone responds and the more closely the cooling loads follow the heat gains. Generally speaking, the zone responds more slowly when either the thermal mass of the zone is increased or when any resistance between the heat gain and the thermal mass is decreased. For example, in Figure 7.4, when comparing the lightweight and heavyweight zones without carpeting, the heavyweight zone responds much more slowly

|  | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 |

than the lightweight zone, due to a significant amount of heat gain being stored in the heavyweight zone's structure. The third curve, for a heavyweight zone with carpeting, reveals that the zone now acts much more like a lightweight zone than a heavyweight zone. Additional factors that might be considered include the following:

- Furniture-furniture acts as an internal thermal mass that can store energy, so it can slow the response of the zone. However, furniture that intercepts solar or thermal radiation and is less thermally massive than the floor can speed the response of the zone; this is usually the dominant factor. The RTFs tabulated in Tables 7.11 and

Table 7.11 Representative Nonsolar RTS Values for Light to Heavy Construction

## Fundamentals of the Radiant Time Series Method

7.12 assumed the presence of furniture with a surface area of 225 ft or $1 / 2$ of the floor area. In turn, $50 \%$ of the beam solar radiation was assumed to be intercepted by the furniture, and the remainder was incident on the floor. This has a mitigating effect on the energy stored in the floor. With the RTF generation spreadsheet, it is possible to set any level of furniture. For rooms with significant window area and an uncarpeted massive floor, eliminating the furniture may noticeably reduce the peak cooling load. However, given the limited knowledge of future placement of furniture in the space, prudence is suggested.

- Carpeting-carpeting limits the amount of energy that can be stored in the floor, speeding the response of the zone.
- Zone geometry and construction-for purposes of computing the RTF, specifica-

Table 7.13 Representative Zone Construction for Tables 7.11 and 7.12
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Table 21)

| Construction Class | Exterior Wall | Roof/ Ceiling | Partition | Floor | Furnishing |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Light | Steel siding, 2 in. insulation, air space, $3 / 4$ in. gyp | 4 in. <br> LW concrete, ceiling air space, acoustic tile | 3/4 in. gyp, air space, 3/4 in. gyp | Acoustic tile, ceiling air space, 4 in. LW concrete | 1 in. wood @ $50 \%$ of floor area |
| Medium | 4 in. face brick, 2 in. insulation, air space, 3/4 in. gyp | 4 in. HW concrete, ceiling air space, acoustic tile | 3/4 in. gyp, air space, 3/4 in. gyp | Acoustic tile, ceiling air space, 4 in. HW concrete | 1 in. wood @ $50 \%$ of floor area |
| Heavy | 4 in. face brick, air space, 2 in. insulation, 8 in. HW concrete, 3/4 in. gyp | 8 in. HW concrete, ceiling air space, acoustic tile | 3/4 in. gyp, <br> 8 in. HW <br> concrete block, <br> 3/4 in. gyp | Acoustic tile, ceiling air space, 8 in. HW concrete | 1 in. wood <br> @ $50 \%$ of <br> floor area |

1. Surface layers are listed in order from the outside of the room to the inside of the room.
2. Carpet, when specified in Tables 7.11 and 7.12 , has no thermal mass and a resistance of $2.73 \mathrm{ft}^{2} \cdot \mathrm{~h} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}$.
3. The test zone is $15 \cdot 30 \cdot 9 \mathrm{ft}$ high. Zones labeled Interior Zones in Table 7.11 have only interior partitions and no exterior walls or fenestration. The other RTFs are based on a test zone with one exterior wall, 30 ft long. The $\%$ glazing is the $\%$ of area on the exterior wall covered by glazing.

Figure 7.4 RTFs (solar) for three zones.

tion of the zone geometry and construction controls the response of the zone only. For example, choosing a higher percentage of fenestration replaces the wall, which may be thermally massive, with glazing, which has negligible thermal mass. This would speed the response of the zone.

## Example 7.3 RTF Determination

The ASHRAE headquarters building in Atlanta, Georgia has a $130 \mathrm{ft}^{2}$ office in the southwest corner of the second floor. Figure 7.5 shows a plan view of the office. Figure 7.6 shows two elevation views of the building. The exterior vertical walls are composed of a spandrel curtain wall construction, a brick wall construction, and windows. The acoustical tile is approximately even with the top of the second-floor windows, and the space above the acoustical tile serves as a return air plenum. Layer-by-layer descriptions of all constructions are given in Table 7.14; surface areas and absorptivities are summarized in Table 7.15. (Note: There is additional discussion of the zone and building in Chapter 8.) The southeast façade has a glazing fraction of $34 \%$, and the southwest façade has a glazing fraction of $44 \%$.

Determine the RTFs from Tables 7.11 and 7.12 and then using the spreadsheet RTF generation tool.

Solution: When viewing Figure 7.5, immediately note that, from the exterior, the geometry of the room is relatively complex, with the brick-clad portion of the façade being oriented at $45^{\circ}$ angles to the other surfaces. Furthermore, as shown in Figure 7.6, there is a large overhang around the building. The first choice the engineer has to make is how to draw the boundary of the zone (i.e., will the surface areas be determined at the inside of the room, the outside of the room, or an intermediate point?). Secondarily, how will the brick-clad portion of the façade be represented? The following two important considerations should be kept in mind.

Figure 7.5 ASHRAE headquarters building office plan view.

1 ELEVATION AT CURTAIN WALL VISION AND SPANDREL GLASS

Figure 7.6 Elevation views of the ASHRAE headquarters building.

Table 7.14 Summary of Constructions for Example 7.3

| Layer Number | Brick Clad | Spandrel | Partition | Furniture | Roof | Floor |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | F01 | F01 | F02 | F02 | F01 | F03 |
| 2 | M01 | F09 | G01 | G05 | F13 | F16 |
| 3 | M02 | F04 | F04 | F02 | I06 | F05 |
| 4 | $107^{*}$ | 107* | G01 |  | F03 | F08 |
| 5 | G01 | G01 | F02 |  |  | M18 |
| 6 | M02 | F02 |  |  |  | F17 |
| 7 | F02 |  |  |  |  | F03 |

1. Layer codes are taken from Table 7.5, except where marked with an asterisk ( ${ }^{*}$ ). These surfaces are as follows:

107 is R-12.5 insulation board, otherwise equivalent to 104.
M18 is 5 in . of lightweight concrete, otherwise equivalent to M11.
2. Layers are specified from outside to inside.

First, at this point in the load calculation process, we are seeking the response of the zone to heat gains. The overhang and the construction of the building above the acoustical ceiling tile have little or no effect on the zone response. The two-dimensional nature of the brick-clad portion may have a slight effect on the response, yet neither the RTF generation procedure nor any of the cooling load calculation
procedures presented in this manual have an explicit way to account for such a construction. If desired, the limiting cases (area of brick-clad construction based on inside area and area of brick-clad construction based on outside area) could be examined with the one-dimensional RTF generation procedure.

Second, conduction heat gains will have a relatively small impact on the zone cooling load compared to solar heat gains through fenestration and internal heat gains. At the point where conduction heat gains are calculated, the same choices must be made. Again, the relative sensitivity to the choice of zone boundary can be checked with one-dimensional procedures, but engineering judgment should be used with regard to the time and effort spent on the representation of the zone. For example, the shading of the windows by the overhang will be considerably more important than conduction heat gain through the overhang side walls, and effort should be spent accordingly.

Given all of the above, for purposes of the example, the areas are calculated based on the inside room boundary, with the room being 9 ft high, measured from the top of the floor to the bottom of the acoustical tile. As a check, the RTFs will also be computed using the outside surface areas.

To choose the correct set of RTFs from Tables 7.11 and 7.12, it is necessary to compare the constructions. The office has a 5 in . lightweight (LW) concrete floor, which would be closest to the lightweight construction in Tables 7.11 and 7.12. However, as the floor is carpeted and the room has furniture, matching it exactly will be less important. The brick portion of the exterior wall is relatively close to the medium-weight construction. The window and spandrel are both very lightweight constructions. As a percentage of the total vertical wall area, the office is approximately $50 \%$ lightweight partition, $27 \%$ window and spandrel, and $23 \%$ brick, or, lumping the partition, window, and spandrel together as lightweight constructions, about $77 \%$ lightweight $/ 23 \%$ brick. For the medium-weight tabulated zone with $50 \%$ glazing on one exterior wall, the total vertical wall area would be $66 \%$ lightweight partition, $17 \%$ window, and $17 \%$ brick, or $83 \%$ lightweight/ $17 \%$ brick. The office roof construction matches the tabulated lightweight zone best, though the fact that the mass in the roof is separated from the room by the acoustical tile and air space renders the match less important.

The above considerations suggest that a tabulated zone with $50 \%$ glazing (on the one exterior wall) and carpeting would be appropriate, and either the mediumweight or lightweight zone would be the best choice, with the medium-weight zone perhaps being the slightly better choice.

For generating custom RTFs, the spreadsheet Example 7.3 RTF Generation.xls may be used. Sample input parameters are shown in Figure 7.7. After entering the input parameters, the RTFs are computed by clicking on the button labeled GENERATE $R T F$. In order to check the sensitivity to the choice of inside area versus outside area, two different worksheets are included, Example 7.3 Inside A and Example 7.3 Outside $A$, respectively.

Finally, the various sets of RTFs may be compared. Figure 7.8 shows the nonsolar RTFs: generated with the outside areas (RTFG-O), generated with the inside areas (RTFG-I), determined from Table 7.11 for a carpeted room with $50 \%$ exterior glazing on the one exterior wall and assuming the medium-weight construction (Tables-MW), and assuming a lightweight construction (Tables-LW). An equivalent comparison is shown for the solar RTFs in Figure 7.9. As can be seen, there is essentially no difference between the two different methods of calculating the surface areas. The approximations that are inevitable when choosing an equivalent zone from the tables do result in an observable but small difference. In the next example, the sensitivity of the cooling load to these small differences in RTFs will be examined.

Fundamentals of the Radiant Time Series Method

## Example 7.4 Cooling Load Calculation

For the office described in Example 7.3, determine the cooling load resulting from a $1 \mathrm{~W} / \mathrm{ft}^{2}$ equipment heat gain (computers and video projectors-assume $20 \%$ radiative) occurring between 8:00 a.m. and 5:00 p.m. Compare the cooling loads resulting from the four slightly different sets of nonsolar RTFs developed in Example 7.3.

Solution: The hourly equipment heat gains are split into radiative and convective portions. Based on the given radiative/convective split, during the hours between 8:00 a.m. and 5:00 p.m., the hourly radiative heat gain is $89 \mathrm{Btu} / \mathrm{h}$ and the hourly convective heat gain is $355 \mathrm{Btu} / \mathrm{h}$. The radiative heat gains are converted to cooling loads with the RTFs and then added to the convective heat gains to determine the total cooling load for each hour. As an example, consider the cooling load at 2:00 p.m., using the RTFs for the medium-weight zone (Tables-MW in Figure 7.8). The radiative portion of the cooling load is determined with Equation 7.4:

$$
\begin{aligned}
& 0.49(89)+0.17(89)+0.09(89)+0.05(89) \\
&+0.03(89)+0.02(89)+0.02(0.0)+0.01(0.0) \\
& Q_{14, \text { radiative }=}= 0.01(0.0)+0.01(0.0)+0.01(0.0)+0.01(0.0) \\
& \vdots \\
&+0.0(89)+0.0(89)+0.00(89)+0.0(89)
\end{aligned}
$$

azarñasim
resulting in a value of $Q_{14, \text { radiative }}=75 \mathrm{Btu} / \mathrm{h}$.
The convective portion of the cooling load is equivalent to the convective portion of the heat gain: $355 \mathrm{Btu} / \mathrm{h}$. Then, the total cooling load is simply the summation of the radiative and convective portions:

$$
Q_{14}=Q_{14, \text { radiative }}+Q_{14, \text { convective }}=75+355=430 \mathrm{Btu} / \mathrm{h}
$$

Calculations for every hour and all four sets of RTFs developed in Example 7.3 are performed in the spreadsheet Example 7.4 ClgLoad from heat gain.xls. These results are summarized in Table 7.16. All four sets of RTFs give approximately the same peak loads, with the tabulated RTFs giving peak cooling loads within about $2 \%$ of the custom-generated RTFs in this case. Figure 7.10 illustrates the hourly heat gains and cooling loads calculated with the custom-generated RTFs and tabulated RTFs corresponding to the medium-weight zone.

While it would be rash to reach a conclusion on the accuracy of the tabulated RTFs based on a single case, the accuracy is certainly acceptable for this case. For cases where there is no clear match to the tables, users should consider using the RTF generation spreadsheet.

### 7.9 Implementing the RTSM

The RTSM method may be implemented in a spreadsheet or as a separate computer program. The spreadsheet may be constructed in an infinite number of ways, to be more or less automated, depending on the desires of the user. The use of macros can simplify the implementation by eliminating the need for coding individual equations in each cell.

Table 7.16 Summary of Results for the Four Sets of RTFs Developed in Example 7.3

| Hour | Heat Gain, <br> Btu/h | Cooling Load, Btu/h |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

| 23 | 0 | 7 | 8 | 9 | 8 |
| 24 | 0 | 6 | 7 | 8 | 6 |

The implementation follows the flow chart shown in Figure 7.1. After geometry, constructions, environmental design conditions, peak internal heat gains and schedules, etc. have been determined, the steps may be summarized as follows:

1. Determine conduction time series factors (CTSFs) for exterior walls and roofs. There are two approaches for determining the CTSFs:
a. If a sufficiently close match to one of the walls or roofs in Tables 7.3 and 7.4 can be found, CTSFs may be taken directly from the tables. To avoid retyping the numbers, spreadsheet 7-3_tabulated_CTSF.xls contains a simple database that can extract any set of CTSFs from the tables.
b. Alternatively, CTSFs may be computed for any combination of onedimensional layers using the methodology utilized in the spreadsheet 7-4_generate_CTSF.xls. If the wall or roof has thermal bridges, the methodology in Appendix E should be used to determine an equivalent layer-by-layer description.
2. Based on the number of panes, the normal SHGC, and the U-factor and window description provided by the manufacturer, determine the appropriate window types and resulting angle correction factors from Table 7.9 or 3.8.
3. Determine RTFs for the zone. There are two approaches:
a. Choose an approximately equivalent zone in Tables 7.11 and 7.12 and use the tabulated sets of RTFs. Spreadsheet 7-6 RTF_tabulated.xls contains a simple database that can extract any set of RTFs from the tables.
b. Compute custom RTFs for the zone using the methodology demonstrated in the spreadsheet Example 7.3 RTF Generation.xls.
4. Calculate hourly solar irradiation incident on each exterior surface and the hourly sol-air temperature for each surface using the methodology described in Appendix D and demonstrated in the spreadsheet 7-1-solar.xls.
5. Compute hourly conductive heat gains from exterior walls and roofs using Equation 7.2 for each hour and the 24 hourly values of sol-air temperature. This is demonstrated in the spreadsheet Example 7.1 Conduction.xls.
6. Compute hourly heat gains from fenestration. This includes:
a. Compute the conduction heat gains using Equation 7.3 and the outdoor air temperature for each hour.
b. Compute the solar heat gain corresponding to beam and diffuse irradiation for each hour using the procedure described in Section 7.5.

Figure 7.10 Space radiant heat gain and cooling load for Example 7.4.
7. Compute hourly internal heat gains from occupants, equipment, and lighting, based on peak heat gains and schedules determined in the initial data-gathering phase.
8. Compute infiltration heat gains based on the procedures described in Chapter 5.
9. Split all heat gains into radiative and convective portions using the recommendations in Table 7.10.
10. Convert radiative portion of internal heat gains to hourly cooling loads using Equation 7.5. The beam solar heat gain will be converted using the solar RTFs; all other heat gains will be converted with the nonsolar RTFs.
11. For each hour, sum convective portions of heat gains with radiative cooling loads. This will be the hourly sensible cooling.

The above steps are suitable for most zones for which the RTSM is suitable. All surfaces are assumed to be of two types: exterior, with associated heat gains, or interior, with no net heat gains. A common exception is the zone with an adjacent uncontrolled space, such as a return air plenum, attic, basement, etc. Treatment of uncontrolled spaces is covered in Appendix F. Chapter 8 demonstrates two approaches to the use of the RTSM for a case with a return air plenum. A general-purpose RTSM spreadsheet is described in Appendix B.

## Application of the RTSM—Detailed Example

This chapter gives a start-to-finish example of applying the radiant time series method (RTSM) for a single zone in the ASHRAE headquarters building-the office introduced in Chapter 7. The headquarters building underwent substantial renovation starting in 2007, and the description here is largely based on the post-renovation state of the building.
The chapter is organized by first presenting the building (Section 8.1) and office (Section 8.2), then presenting the application of the RTSM for the following cases:

1. First, for the case with no interior shading, all of the steps are presented with intermediate values (Section 8.3). In this section, the return air plenum is treated by use of an estimate regarding the percentage of roof heat gain that goes directly to the return air.
2. Second, the case with light-colored venetian blinds (Section 8.4) is considered.
3. An alternative approach to calculating the effect of the return air plenum (Section 8.5) is presented. Here, the hourly air temperature in the return air plenum is estimated and used to estimate the heat gain through the acoustic tile to the room.

### 8.1 Building Overview

The ASHRAE headquarters building is a two-story, approximately $35,000 \mathrm{ft}^{2}$ office building located in Atlanta, Georgia, at $33.8^{\circ} \mathrm{N}$ latitude and $84.5^{\circ} \mathrm{W}$ longitude. Figures 8.1 and 8.2 show floor plans for the building. Figures 8.3 and 8.4 show elevation views.

The building has a curtain wall construction, with the exterior walls alternating between brick pilasters and window/spandrel glass sections.

The following information for the windows is interpreted from the original manufacturer's data; the windows are similar to glass type 5D in Table 3.7, but not exactly the same:

- Double-glazed window with a $1 / 4 \mathrm{in}$. bronze-tinted outer pane, $1 / 2 \mathrm{in}$. air space, and $1 / 4 \mathrm{in}$. clear indoor pane.
- The windows are nonoperable and mounted in aluminum frames with thermal breaks. The overall combined U-factor is estimated to be $0.56 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$.
- The normal solar heat gain coefficient (SHGC) is given as 0.56 .
- The visual transmittance is given as 0.48 .
- Light-colored interior miniblinds are installed.

The values for U-factor, normal SHGC, and visual transmittance have all been given without reference to window sizes, so they may be inferred to be center-of-glass values.

Lighting is done with pendant fluorescent fixtures.

### 8.2 Office Details

The ASHRAE headquarters building in Atlanta has a $143 \mathrm{ft}^{2}$ office in the southwest corner of the second floor. Figure 8.7 shows elevation views of the office roof overhang and windows. Figure 8.5 shows a plan view of the office.

The geometry of the building was discussed in Example 7.3. Because of the complex geometry, some approximations will be made, particularly for the brick-clad pilasters. The office has southeast- and southwest-facing exterior vertical walls composed of spandrel curtain wall construction, brick-clad pilasters, and windows. The

[^10]

Figure 8.4 Elevation views of the building.
southeast façade has a glazing fraction of $25 \%$, and the southwest façade has a glazing fraction of $32 \%$. The acoustical tile is approximately even with the top of the second floor windows, and the space above the acoustical tile serves as a return air plenum. The return air plenum complicates the load calculation. An initial approximation is that the return air plenum removes $30 \%$ of the cooling load due to roof heat gains. In many cases, return air plenums will also remove a fraction of the lighting heat gain, but with pendant fixtures no fraction of the lighting heat gain will be removed.

Layer-by-layer descriptions of all constructions are given in Table 8.1; surface areas are summarized in Tables 8.2a and 8.2b. A few notes on how the drawings shown in Figure 8.5 are represented by the layer-by-layer descriptions in Table 8.1 may be helpful:

- Brick-clad pilaster-The complex geometry of the brick pilaster must be rendered in one-dimensional form before it can be analyzed with standard load calculation

Figure 8.5 Office plan view.

Table 8.1 Office Construction Data

| Layer No. | Brick Clad | Spandrel | Partition | Furniture | Roof | Floor |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Note: Horizontal and vertical overhang dimensions correspond to Figure D. 3 in Appendix D.
methods. A detailed numerical analysis could possibly be used to come up with the best possible one-dimensional representation of the wall, but it is hard to imagine a situation where that would be feasible. Instead, given the expected small heat gains due to conduction through exterior walls (compared to internal heat gains and fenestration heat gains), this will be approximated as a one-dimensional wall of area equivalent to the inside area but with material layers based on the actual construction. Furthermore, the inside of the column is filled with insulation, but in an irregular shape. The insulation is rated at R-3 in. per inch of thickness, and an estimate of a mean thickness of around 3 in.or a little more suggests treating the insulation as being R-10. Note that, when choosing between insulation layers given in Table 7.5 , the thermal mass of the insulation is insignificant. Thus, choosing any insulation type that gives a unit thermal resistance of R-10 should be sufficient.

- Spandrel wall-The spandrel wall is relatively simple compared to the brick-clad pilaster, but it presents its own minor difficulties. Specifically, the placement of the batt insulation is a little unclear in the original drawings. Furthermore, the steel

## Load Calculation Applications Manual (I-P), Second Edition

studs will create thermal bridges for which we might be justified in using the approach described in Appendix E to account for their effect. However, considering the relatively small effect of conduction on the total cooling load and the presence of rigid board insulation that covers the studs and reduces the impact of the thermal bridges, the simple approximation shown in Table 8.1 is made. The approximation includes neglecting the impact of the thermal bridge, combining the two layers of insulation into one R-10 layer, and neglecting two additional air spaces that may or may not exist everywhere the spandrel glass construction is used.

- Partition-The partitions, which consist of gypsum board screwed to steel studs, are modeled as two layers of gypsum board separated by an air space. Since they are not exterior surfaces, their only influence is on the thermal storage of the zone.
- Furniture-The furniture is almost always an unknown. Even if there is some knowledge of what will be initially installed, occupants are likely to move or change it over time. Given this uncertainty, coupled with the difficulty in precisely describing even the simplest furniture and the small influence that furniture generally has on the cooling load, a simple approach is taken here. A 1 in . thick layer of wood with surface area equal to the floor area would be approximately equivalent to a table taking up one half of the floor area or a smaller table and chairs. (The area specified is the exposed area of the table, meaning both the top and bottom sides.)
- Roof-Since we are using the simple approximation that the effect of the return air plenum is simply to move $30 \%$ of the cooling load due to the roof from the zone to the return air, we will treat the return air plenum as part of the zone. Hence, the description shown in Table 8.1 does not include the air space or acoustical tile. Also, the exterior wall areas include the wall portions above the acoustical tile, in the return air plenum, which is approximately 3.5 ft high.
- Floor-The floor is a carpeted 5 in. concrete slab poured on a metal deck above an air space and acoustical tile.

As discussed in Example 7.3, the geometry of the room is, from the exterior, relatively complex, with the brick-clad portion of the façade being oriented at $45^{\circ}$ angles to the other surfaces. Noting that the brick façade will represent a fairly small part of the overall heat gains, a simple approximation of treating the brick façade as if it has a surface area corresponding to the inside surface area can be justified. Therefore, the inside areas taken from Example 7.3 will be used to represent each of the surfaces, with the exception that gross wall areas will include those parts above the acoustical tile. On the outside of the building, above the level of the acoustic tile, there is an overhang. For simplicity in this example, we have simply computed the gross outside surface areas as if the spandrel and brick extend to the roof. These areas are summarized in Tables 8.2 a and 8.2b. Table 8.2a shows the surface facing directions (degrees clockwise from north), tilt angles (degrees from horizontal), surface solar absorptances, and surface boundary conditions (TOS = outside of surface is exposed to the outside sol-air temperature; TA = outside of surface is exposed to another conditioned space).

Table 8.2b summarizes the window properties and Table 8.2c summarizes the exterior shading geometry.

### 8.3 Office Example— RTSM

Figure 7.1 shows a flowchart for application of the RTSM. The method might broadly be divided into five steps:

1. Preliminary selection of coefficients (conduction time series factors [CTSFs], radiant time factors [RTFs], and solar heat gain coefficients [SHGC] and angle correc-
tion factors); determination of outdoor environmental conditions (hourly air temperatures, sol-air temperatures, and incident solar radiation); determination of indoor environmental conditions
2. Computation of heat gains
3. Splitting of heat gains into radiative and convective components
4. Conversion of radiative heat gains to cooling loads
5. Summation of cooling loads due to radiative and convective heat gains

Sections 8.3.1-8.3.5 discuss each of the steps in turn.

### 8.3.1 Selection of Coefficients and Determination of Environmental Conditions

## Conduction Time Series Factors (CTSFs)

The office has three exterior construction types: brick-clad wall on the southeast and southwest façades, spandrel wall on the southeast and southwest façades, and the roof. Several different approaches for determining CTSFs were used in Example 7.1. In this case, compute the CTSFs using the spreadsheet Example 8.1 Compute CTSF.xls available on the online supporting files accompanying this manual. The resulting CTSFs are summarized in Table 8.3. Note that rounding the CTSFs to two or three significant digits will often result in the CTSFs not summing to one. Using three significant digits, as in Table 8.3, gives summations that are within $0.1 \%$ of one; this is equivalent to an error in the U-factor of $0.1 \%$. This is insignificant compared to other uncertainties in the load calculation.

## Radiant Time Factors (RTFs)

The RTFs for this zone were computed in Example 7.3. Two approaches, determination of RTFs from look-up tables and use of a spreadsheet to generate RTFs for the specific zone, were examined. In addition, the zone geometry was specified based on both outside areas and inside areas. As shown in the example, all approaches gave similar results. Here, we will adopt custom-generated RTFs based on the zone gross areas (Table 8.2a). The calculated values are shown in Table 8.4 and may be compared to those calculated in Example 7.3-the RTFs are quite close but not exactly the same. These are taken from the spreadsheet Example 8.1 Compute RTF.xls.

## Solar Heat Gain Coefficients (SHGCs) and Angle Correction Factors

The windows, as described in Section 8.1, have a normal SHGC of 0.56, and the closest fenestration type in Table 3.7 is 5 d . The angle correction factors are taken from Table 3.8 and are summarized in Table 8.5. We will consider the cooling load both with and without interior shading using light-colored venetian blinds. With no interior shading, the interior attenuation coefficient (IAC) is 1 , and the radiative fraction for beam and diffuse solar heat gains is $100 \%$. With light-colored venetian blinds, the IAC can be taken from Table 3.9 b for glass type 5D. While heat gains may be chosen for a range of louver positions, here we are assuming the louvers positioned at $45^{\circ}$. In that case, $\mathrm{IAC}_{0}=0.74$, $\mathrm{IAC}_{60}=0.65, \mathrm{IAC}_{\text {diff }}=0.79$ and the radiative fraction can be taken from the same table as 0.54 .

## Design Air Temperatures

For this example, we will use the Atlanta 5\% July design conditions. Atlanta design conditions are taken from Table 4.1. Information taken from Table 4.1 includes the following:

- Latitude: $33.64^{\circ} \mathrm{N}$
- Longitude: $84.43^{\circ} \mathrm{W}$
- Peak dry-bulb temperature: $91.9^{\circ} \mathrm{F}$ ( $5 \%$ monthly cooling condition for July, which is the hottest month)
- Mean coincident wet-bulb temperature: $74.4^{\circ} \mathrm{F}$
- Mean daily temperature range: $20.5^{\circ} \mathrm{F}$

Knowing the peak dry-bulb temperature and mean daily temperature range, Table 4.2 can be used to determine the hourly air temperatures. Instead, Equation 4.1 is used here and the resulting air temperatures are summarized along with sol-air temperatures in Table 8.7.

The inside design air temperature is chosen to be $75^{\circ} \mathrm{F}$, with a relative humidity of $50 \%$.

## Incident Solar Radiation and Sol-Air Temperatures

Outdoor air temperature is computed with Equation 4.1. Incident solar radiation and sol-air temperatures are computed using the procedures described in Appendix D, where all relevant equations are given. The spreadsheet Example 8.1 solar.xls is used to determine incident solar radiation, shown in Table 8.6, for the southeast-facing wall, the south-west-facing wall, and the horizontal roof. It also determines hourly air temperature, and sol-air temperatures on the same three surfaces, as shown in Table 8.7.

To determine the values in Tables 8.6 and 8.7, it is necessary to choose the following parameters in addition to those listed immediately above:

## Load Calculation Applications Manual (I-P), Second Edition

- Time convention: can be chosen as local time or solar time. Local time is used here. For convenience when specifying internal heat gain schedules, it is best to use local time.
- The solar absorptance affects the results in Table 8.7 only. (Table 3.3 gives typical values.) For spaces such as this, where the walls and roof have moderate amounts of insulation and where most of the cooling loads will come from fenestration and internal heat gains, the solar absorptances will have a relatively small effect on the cooling load. The solar absorptance of the roof will have the greatest effect. The roof has a low solar absorptance ( 0.45 ) but given the possibility that, over time, the roof will become soiled regardless of the roof coating, a value of 0.9 is chosen. The walls may also have slightly lower absorptances, but a value of 0.9 is chosen as a conservative estimate.
- An exterior surface conductance of $4.0 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$, corresponding to summer design conditions, was selected.
- Optical depths taub and taud are taken from Table 4.1 as 0.440 and 2.202 , respectively.
- Ground reflectance: a typical value of 0.2 is taken.

### 8.3.2 Computation of Heat Gains

With all of the preliminaries out of the way, we are ready to begin computing the heat gains. Most of the difficulties requiring engineering judgment are now over, and what remains is mostly straightforward calculation. First, conduction heat gains for each surface are computed, then solar heat gains from fenestration, internal heat gains, and finally, infiltration heat gains.

## Conduction Heat Gain from Opaque Surfaces

The conduction heat gain from each surface is computed with Equation 7.1 as illustrated in Example 7.1. The values required to evaluate Equation 7.1 are taken from the following:

- Areas: Table 8.2
- U-factors: Table 8.3
- CTSFs: Table 8.3
- Sol-air temperatures: Table 8.7

The spreadsheet Example 8.1 Conduction HG.xls is used to perform the calculation. The resulting heat gains are shown in Table 8.8. A comparison of the numbers shows that the roof, because of its large area, has significantly higher heat gains than the other surfaces.

## Fenestration Heat Gains

There are two types of heat gains associated with the windows-conduction heat gains and solar heat gains. Because the thin layers of glass used in windows have relatively low thermal capacitance, the conduction heat gain can be analyzed on a steady-state basis. As noted earlier, the manufacturer's data are all for center-ofglass only. Ideally, framing effects would be included; they would tend to increase heat loss under heating load conditions and increase conduction heat gain under cooling loads but decrease solar heat gains under cooling load conditions. Tables 3.6a and 3.6b give corrected U-factors for a range of glass and frame combinations. This may be used to roughly estimate the combined U-factor if manufacturer's data are not available.

For this example, the manufacturer's data are simply applied to the total window area (including the frame). Under cooling load conditions, where the solar heat gains are considerably larger than the window conduction heat gains, this approximation is expected to slightly overpredict the peak cooling load. The U-factor given by the manufacturer$0.56 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$-coupled with the window areas given in Table 8.2 b , the outdoor air

temperatures given in Table 8.7, and an inside room air temperature of $75^{\circ} \mathrm{F}$ are used with Equation 7.3 to determine the window conduction heat gains given in Table 8.9.

The solar heat gains are computed with the procedure illustrated in Example 7.2, although they are for a window of different size and different shading geometry. Table 8.10a shows the solar angle calculations and incident beam and diffuse radiation for daylight hours. The apparent solar time, hour angle, solar altitude angle, solar azimuth angle, surface solar azimuth angle, and incident angle are computed with the referenced equations from Appendix D. The incident beam and diffuse radiation values are calculated with the ASHRAE clear-sky model, covered in Section D. 2 of Appendix D, with the same assumptions as discussed in conjunction with Table 8.6.

Table 8.10 b gives the intermediate results for the exterior shading calculations. Up to the point of finding the sunlit and shaded areas of the window, the procedure follows Appendix D, using the referenced equations. The beam SHGC is determined by interpolating the angle correction factors in Table 8.5 for the corresponding incidence angles given in Table 8.10a, then multiplying by the normal SHGC taken from Table 8.2 b . Then, the beam solar heat gains (next-to-last column) are calculated by multiplying the sunlit area by the incident beam radiation and the interpolated SHGC, as described in Section 7.5. The diffuse solar heat gains (last column) are calculated by multiplying the total window area by the incident diffuse radiation and the diffuse SHGC given in Table 8.6. Without interior shading, the last two columns of Table 8.10b give the beam and diffuse solar heat gains.

The calculations are repeated for the southeast-facing windows; the results are given in Tables 8.11a and 8.11b.

## Internal Heat Gains

Internal heat gains are typically specified for each hour as a combination of a peak heat gain rate and an hourly, fractional schedule. First, a reasonable estimate of the maximum number of people for the office must be made. We will assume that

| 24 | 55 | 55 | 111 |

there is one person with a sensible heat gain of $250 \mathrm{Btu} / \mathrm{h}$ and a latent heat gain of $200 \mathrm{Btu} / \mathrm{h}$. This corresponds to moderately active office work adjusted for a typical male/female ratio, as shown in Table 6.1. The peak occupancy rate (in this case, one person) is then adjusted on an hour-by-hour basis, according to the schedule shown in Table 8.12. For purposes of making the load calculation, some reasonable assumptions must be made about the schedule of operation. Here, we have assumed that the building will be fully in operation between about 7:30 a.m. and 5:30 p.m. and, as a result, the people, lighting, and equipment fractions are set to be 1 for hours 9-17 and 0.5 for hours 8 and 18 . During the remainder of the day, it is assumed that there will be no occupants present but that lighting and equipment will have about $10 \%$ of their peak heat gain from some lights and equipment remaining on and/or being in standby condition.

Lighting heat gain has been set at 110 W , based on the specified lighting fixture. As discussed above, an equipment heat gain of 130 W , based on a desktop computer, flat-panel monitor, and multifunction personal printer has been determined. We have assumed no equipment latent heat gain, as would be expected for office equipment.

Like occupant heat gains, the peak values are modified by the fractional schedules given in Table 8.12. A single occupant is expected for this office. Multiplying the peak heat gains by the fractional schedules in Table 8.12 gives the hourly internal heat gains shown in Table 8.13.

## Infiltration Heat Gains

An infiltration rate of 25 cfm has already been determined. Then, the sensible heat gain is determined with Equation 5.4, and the latent heat gain is determined with Equation 5.5. The resulting heat gains are summarized in Table 8.14. For purposes of determining the latent heat gain, the indoor design condition of $75^{\circ} \mathrm{F}, 50 \%$ relative humidity corresponds to a humidity ratio of $0.0096 \mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$. The outside humidity ratio is calculated for each hour, based on the hourly dry-bulb and wet-bulb temperatures shown in the table. For both states, the humidity ratios have been computed based on barometric pressure ( 14.16 psia ) taken from Table 4.1.

## Summary

Table 8.15 summarizes the sensible heat gains presented in Tables 8.8-8.13 for the initial case of no interior shading (venetian blinds) on the windows. The
wall conduction is simply the sum of the conduction heat gains for the four walls presented in Table 8.8. The roof conduction heat gain comes from Table 8.8 but is only the $70 \%$ presumed to reach the space. (The other $30 \%$ is presumed to be transferred directly to the return air.) The window conduction heat gain comes from Table 8.9. The window beam solar heat gain and diffuse solar heat gain are found from adding the last two columns of Tables 8.10 b and 8.11 b . The people and equipment heat gains come directly from Table 8.13. The lighting heat gains in Table 8.13 represent the total heat gain to the space and the return air plenum. In Table 8.15, the values from Table 8.13 have been multiplied by the fraction going to the space, $100 \%$ for pendant-type lighting. The infiltration heat gains come from Table 8.14.

Table 8.16 summarizes the latent heat gains from Tables 8.13 and 8.14. Because the latent heat gains are all assumed to be met by the cooling system during the hour in which they occur, these are equivalent to the latent cooling loads.

### 8.3.3 Splitting of Sensible Heat Gains into Radiative and Convective Components

Once all of the sensible heat gains have been determined, the next step in the RTSM is to split them into radiative and convective components. The radiative fractions for each component are as follows:

- Wall conduction: $46 \%$, from Table 7.10
- Roof conduction: $60 \%$, from Table 7.10
- Window conduction: $46 \%$, from Table 7.10
- Window beam and diffuse solar: $100 \%$, from Table 7.10 (for windows without interior shading. For the case with light-colored venetian blinds, the radiative fraction will be $54 \%$.)
- People: $60 \%$, from Table 7.10 (Table 6.1 covers a range of conditions.)
- Office equipment: $15 \%$. It is expected that the equipment will be predominantly fan-cooled (computers and video projector). However, flat-panel display monitors will not be fan-cooled, so the value of $15 \%$ represents an intermediate value between the two options ( $10 \%$ radiative for fan-cooled, $30 \%$ radiative for non-fancooled, as shown in Table 7.10).
- Lighting: $57 \%$ for pendant fixtures (non-in-ceiling fluorescent luminaire from Table 6.3). This is $57 \%$ of the space fraction, which here is $100 \%$ of the lighting heat gain.
- Infiltration: 0\%, from Table 7.10

Applying these radiative fractions to the heat gains given in Table 8.15 yields the values given in Table 8.17. The rest of the heat gains are convective and summarized in Table 8.18.

### 8.3.4 Conversion of Radiative Heat Gains to Cooling Loads

The next step in the RTSM is to convert the radiative heat gains into cooling loads by application of Equation 7.5 with the appropriate set of RTFs from Table 8.4. In short, the nonsolar RTFs are applied to every heat gain type except beam solar radiation. This includes diffuse solar heat gains. The solar RTFs are applied only to the beam solar radiation heat gain. The resulting cooling loads from the radiative heat gains are given in Table 8.19.

### 8.3.5 Summation of Cooling Loads

Now that the radiative heat gains have been converted to cooling loads, the cooling loads for each component can be determined by adding the convective heat gains, which are equivalent to the convective portion of the cooling loads, to the radiative portion of the cooling loads. Once the cooling loads from radiative heat gains are added to the cooling loads from convective heat gains for each component, the resulting sensible cooling loads are given in Table 8.20.

In addition to the sensible cooling loads on the room, there are the latent cooling loads, previously summarized in Table 8.16, and the heat gains to the return air plenum, which are assumed to be instantaneous. These heat gains include $30 \%$ of the roof heat gains and $55 \%$ of the lighting heat gains and are summarized in the first two columns of Table 8.21. The third column gives the total presumed heat gains to the return air. The fourth column gives the system sensible cooling load, which is the room sensible cooling load from Table 8.20 plus the heat gains to the return air. This represents the load on the system from this room. The room sensible cooling load in Table 8.20 would be used to determine the required airflow at a given supply temper-

ature to keep the room at the design temperature, $75^{\circ} \mathrm{F}$. The system sensible cooling load in Table 8.21 would be used to determine the required coil capacity.

### 8.4 RTSM Calculation with Light-Colored Venetian Blinds

Section 8.3 carried the office-cooling load calculation from start to finish for the office without any interior shading of the windows. In this section, the changes in the calculation procedure and results will be briefly discussed.

First, with venetian blinds some assumption must be made regarding their position; here they are assumed to be oriented at $45^{\circ}$. Then the interior attenuation coefficients (IAC) can be taken from Table 3.9b (value varies) and the radiative fraction is 0.54. From Table 3.9b, in the glazing type 5D column, $\mathrm{IAC}_{0}=0.74, \mathrm{IAC}_{60}=0.65$, and $\mathrm{IAC}_{\text {diff }}=0.79$. The IAC for the beam radiation is computed each hour with Equation 3.2; it varies with solar position and the resulting profile angle.

| 23 | 0 | 2 | 2 | 1101 |
| 24 | 0 | -2 | -2 | 864 |

With IAC values determined, the beam and diffuse solar heat gains given in the last two columns of Tables 8.10 b and 8.11 b are multiplied by the IAC, giving the values shown in Table 8.22. The beam and diffuse solar heat gains are added for both windows to get the total heat gains shown in the last two columns of Table 8.22.

The total solar heat gains shown in Table 8.22 must be split into radiative and convective components. A key difference, as can be seen in Table 7.10, is that the radiative fraction for solar heat gains is not $100 \%$ when interior shading is present. Rather, radiative fractions are given for each combination of fenestration and shading in Tables $3.9 \mathrm{a}-3.9 \mathrm{~g}$. For this specific case, a value of 0.54 is given by Table 3.9 b . Applying this fraction to both the beam and diffuse solar heat gains in Table 8.22 gives the radiative and convective components shown in Table 8.23.

Next, the radiative heat gains are converted to the radiative components of the cooling loads (second and third columns of Table 8.24), and the radiative and con-

vective portions of the cooling loads are added together (fourth and fifth columns of Table 8.24). Finally, all of the cooling load components are summed to get the zone-sensible cooling loads, as shown in the sixth column of Table 8.24. Note that all other cooling load components are as shown in Tables 8.19 and 8.20.

Comparison of the solar heat gains between the case without blinds (Table 8.15 ) and the case with blinds (Table 8.22) shows a reduction in diffuse heat gains of $21 \%$ and reductions in beam heat gains from $28 \%$ to $35 \%$. However, comparison of the cooling loads between the two cases does not show a precisely corresponding reduction. For example, the peak cooling load due to beam solar heat gains is $1264 \mathrm{Btu} / \mathrm{h}$ at hour 19 without blinds and $987 \mathrm{Btu} / \mathrm{h}$ at hour 19 with blinds-a $22 \%$ reduction. Physically speaking, this is a consequence of the blinds absorbing the incoming solar radiation and releasing much of it by convection to the room air. This portion of the solar radiation becomes part of the cooling load instantaneously. From the viewpoint of the RTSM calculation, this is accomplished by choosing a lower radiative fraction when the blinds are present. In either case, because the window cooling loads are only about half of the total cooling loads at the peak hour, the overall effect on the zone-sensible cooling load is relatively small (about $400 \mathrm{Btu} / \mathrm{h}$ at hour 17, as shown in Figure 8.6).

## Load Calculation Applications Manual (I-P), Second Edition

### 8.5 RTSM Calculation with Separate Treatment of Return Air Plenum

The office has a return air plenum above the suspended acoustic-tile ceiling. In Sections 8.3 and 8.4 , this was addressed by treating the entire space as one thermal zone, with an assumption that $30 \%$ of the roof heat gains were transferred directly to the return air without becoming part of the room cooling load. These heat gains do, however, show up as part of the system cooling load. The $30 \%$ assumption is fairly arbitrary, and it may be checked with an alternative approach. As discussed in Appendix F, uncontrolled spaces may be analyzed with a quasi-steady-state heat balance. This approach is relatively simple, but its accuracy decreases as the thermal mass in the uncontrolled space envelope increases. In this particular case, there is relatively little thermal mass in either the roof or floor of the return air plenum, and therefore the quasi-steady-state approach is quite adequate.

In this section, a quasi-steady-state heat balance on the return air plenum will be used to estimate the hourly space air temperature in the return air plenum and then to find the resulting heat gain to the occupied space. This example will use windows without interior shading (i.e., the room as described in Section 8.3 will serve as the base case). Treatment of the return air plenum will be described first, in Section 8.5.1. Then, calculation of loads for the room will be described in Section 8.5.2.

### 8.5.1 Computation of Air Temperature in the Return Air Plenum

Finding air temperatures in the return air plenum is similar to the procedure described in Appendix F for an unheated mechanical room. A steady-state heat balance is performed by balancing all of the heat flows into and out of the return air plenum. These include the following:

- Conduction heat transfer from the outdoors through the roof
- Conduction heat transfer from the outdoors through the side walls
- Conduction heat transfer to the room below through the acoustic tile ceiling
- Heat transfer to/from return air from the room
- Heat transfer to/from infiltration air
- Heat gain from the room lighting

Figure 8.6 Comparison of zone-sensible cooling loads, with and without light-colored venetian blinds.

# Application of the RTSM—Detailed Example 

## Conduction Heat Transfer from the Outside via the Roof and Exterior Walls

For each of the exterior surfaces, conduction heat gain to the space is simply given by

$$
\begin{equation*}
q_{c, \text { ext }}=U A \cdot \Delta t=U A \cdot\left(t_{S A}-t_{p}\right) \tag{8.1}
\end{equation*}
$$

where
$t_{S A}=$ the sol-air temperature applying to the surface, ${ }^{\circ} \mathrm{F}$
$t_{p}=$ the plenum air temperature, ${ }^{\circ} \mathrm{F}$
$U A$ values are summarized for each surface in Table 8.25. The value for the roof is taken from Table 8.3. As before, it does not include the acoustic tile or ceiling air space resistances. For the side walls, actual computation of the $U A$ value might include the parapet, but it has been ignored here. The U-factor has been computed for two vertical surface resistances, two layers of gypsum board, and two layers of R-5 insulation, as taken from the original building drawings.

## Conduction Heat Transfer from the Plenum to the Room via the Acoustic Tile Ceiling

Conduction heat loss from the plenum to the room below is given by

$$
\begin{equation*}
q_{c, \text { int }}=U A \cdot \Delta t=U A \cdot\left(t_{p}-t_{r c}\right) \tag{8.2}
\end{equation*}
$$

where $t_{r c}$ is the constant room-air temperature, $75^{\circ} \mathrm{F}$.
The U-factor of the plenum floor, given in Table 8.25, has been computed for two horizontal surface resistances and a single layer of acoustic tile.

## Heat Transfer from the Room to the Plenum via Return Air and Lighting Heat Gain

There is a significant flow of return air from the room into the return air plenum. This air may be heated by the lights while in transit from the room to the plenum. However, the two effects may be treated separately. Return air will be assumed to enter the plenum at the room air temperature, and the lighting heat gain will be added separately. The fact that some of the lighting heat gain may be transferred to the return air then to the plenum, rather than directly to the plenum, has no effect on the plenum air temperature.

There is a significant flow of return air from the room into the return air plenum. The amount of return air has not been determined. For this room, it will be equal to the supply airflow rate, which will depend on the supply air temperature. If a supply air temperature of $59^{\circ} \mathrm{F}$ is chosen, with the peak sensible room cooling load calculated in Section 8.3 ( $5017 \mathrm{Btu} / \mathrm{h}$, shown in Table 8.20), a supply airflow rate of about 285 cfm will be required. Adapting Equation 5.4, the heat gain to the plenum via return air will be

Table 8.25 UA Values for the Return Air Plenum

| Surface | $\boldsymbol{U}, \mathbf{B t u} / \mathbf{h} \cdot \mathbf{f t}^{\mathbf{2} \cdot} \cdot{ }^{\mathbf{F}}$ | $\boldsymbol{A}, \mathbf{f t}^{\mathbf{2}}$ | $\boldsymbol{U A}, \mathbf{B t u} / \mathbf{h} \cdot{ }^{\circ} \mathbf{F}$ |
| :---: | :---: | :---: | :---: |
| Roof | 0.032 | 130 | 4.11 |
| SE side wall | 0.08 | 45.5 | 3.64 |
| SW side wall | 0.08 | 35 | 2.80 |
| Acoustic tile ceiling | 0.275 | 130 | 35.75 |

$$
\begin{equation*}
q_{r a}=C_{s} Q \Delta t=C_{s} Q\left(t_{r c}-t_{p}\right) \tag{8.3}
\end{equation*}
$$

where
$C_{S}=$ sensible heat factor, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{cfm} \cdot{ }^{\circ} \mathrm{F}, 1.1$ is a typical value
$\Delta t=$ temperature difference between the outdoor air and the indoor air, ${ }^{\circ} \mathrm{F}$
Although this is written as a heat gain to the plenum, it will usually be negative, resulting in a heat loss to the plenum. With a flow rate of 285 cfm and using a value of 1.1 for the sensible heat factor, Equation 8.3 can be reduced to

$$
\begin{equation*}
q_{r a}=314\left(t_{r c}-t_{p}\right) \tag{8.4}
\end{equation*}
$$

The lighting heat gain $q_{l t g}$ to the return air plenum has already been determined and can be taken directly from Table 8.21.

## Heat Transfer tolfrom the Outdoors via Infiltration

For sea-level conditions, the infiltration heat gain is given by Equation 5.4 and is adapted to our situation:

$$
\begin{equation*}
q_{i n f}=C_{s} Q \Delta t=C_{s} Q\left(t_{o}-t_{p}\right) \tag{8.5}
\end{equation*}
$$

The infiltration rate to the plenum will be approximately volume weighted and taken to be 7 cfm , in which case Equation 8.5 reduces to

$$
\begin{equation*}
q_{i n f}=7.7\left(t_{o}-t_{p}\right) \tag{8.6}
\end{equation*}
$$

## Heat Balance

The steady-state heat balance can now be expressed in words as "the heat transfer rate into the plenum is equal to the heat transfer rate out of the plenum." Or, it can be expressed in equation form as

$$
\begin{equation*}
\Sigma q_{c, \mathrm{ext}}+q_{\mathrm{inf}}+q_{\mathrm{ra}}+q_{\mathrm{ltg}}=q_{c, \mathrm{int}} \tag{8.7}
\end{equation*}
$$

Substituting Equations 8.1, 8.2, 8.4, and 8.6 into Equation 8.7 then solving for $t_{p}$ gives

$$
\begin{equation*}
t_{p}=\frac{\Sigma U A_{\mathrm{ext}} t_{\mathrm{SA}}+U A_{\mathrm{int}} t_{r c}+7.7 \cdot t_{o}+314 \cdot t_{r c}+q_{\mathrm{ltg}}}{\Sigma U A_{\mathrm{ext}}+U A_{\mathrm{int}}+7.7+314} \tag{8.8}
\end{equation*}
$$

In both Equations 8.7 and 8.8 , the summation simply represents the inclusion of each of the three exterior surfaces: roof, southeast end wall, and southwest end wall. Note that Equation 8.8 is essentially a weighted average of the different boundary temperatures with which the plenum exchanges heat, with the addition of the lighting heat gain to the numerator. The weights are either $U A$ values or sensible heat factors.

The calculation is summarized in Table 8.26. The second row contains the numerical values of the weights for each of the heat transfers. The second through fourth columns hold the sol-air temperatures for each of the three exterior surfaces for each hour. The fifth column is the temperature on the other side of the plenum floor (i.e., the constant room air temperature). The sixth column holds the outdoor air temperatures for each hour; the seventh column holds the return air temperature (again, the constant room air temperature). The eighth column holds the lighting heat gain to the plenum for each hour. Finally, the ninth column holds the calculated plenum temperatures for each hour, based on Equation 8.8.

Table 8.26 Summary of Heat Balance Calculation

| Hour | Boundary Temperatures (Weight, Btu/h ${ }^{\circ} \mathbf{F}$ ) |  |  |  |  |  | Heat <br> Gain $q_{l t g}$ | Plenum$t_{p}$ |

| 15 | 149.7 | 104.4 | 126.9 | 75.0 | 91.2 | 75.0 | 0 | 76.9 |
| 16 | 142.8 | 102.5 | 136.0 | 75.0 | 92.0 | 75.0 | 0 | 76.8 |
| 17 | 131.3 | 100.2 | 138.8 | 75.0 | 91.7 | 75.0 | 0 | 76.7 |
| 18 | 116.2 | 96.8 | 134.1 | 75.0 | 90.2 | 75.0 | 0 | 76.4 |
| 19 | 99.9 | 92.9 | 122.0 | 75.0 | 88.6 | 75.0 | 0 | 76.1 |
| 20 | 84.5 | 88.0 | 100.6 | 75.0 | 86.2 | 75.0 | 0 | 75.7 |
| 21 | 76.2 | 83.2 | 83.2 | 75.0 | 83.2 | 75.0 | 0 | 75.3 |
| 22 | 74.2 | 81.2 | 81.2 | 75.0 | 81.2 | 75.0 | 0 | 75.2 |
| 23 | 72.3 | 79.3 | 79.3 | 75.0 | 79.3 | 75.0 | 0 | 75.1 |
| 24 | 70.5 | 77.5 | 77.5 | 75.0 | 77.5 | 75.0 | 0 | 75.0 |

Looking at the plenum temperatures, they are lower than might be expected. A review of the weights ( $U A$ for surfaces or $\dot{m} C_{p}$ for airflows) shows that the plenum air temperature is dominated by the return air, which holds the plenum air temperature relatively close to the room air temperature.

Now that the return air-plenum air temperatures are known, the heat gain from the plenum to the room can be determined, as can the heat gain to the return air. The heat gain to the room from the plenum is given by Equation 8.2:

$$
q_{c, \text { int }}=U A \cdot \Delta t=U A \cdot\left(t_{p}-t_{r c}\right)=35.75 \cdot\left(t_{p}-t_{r c}\right)
$$

The heat gain to the return air is

$$
\begin{equation*}
q_{r a}=C_{s} Q \Delta t=C_{s} Q\left(t_{p}-t_{r c}\right)=314\left(t_{p}-t_{r c}\right) \tag{8.9}
\end{equation*}
$$

## Load Calculation Applications Manual (I-P), Second Edition

These heat gains are summarized in Table 8.27. A comparison of the heat gains to the room from the plenum (last column of Table 8.27) and the heat gains from the roof to the room when the plenum was not explicitly considered (last column of Table 8.8), suggests that the amount of roof heat gain intercepted by the return air plenum is considerably higher than the $30 \%$ value assumed earlier. Near peak cooling load conditions, the heat gain to the room from the plenum is only about $20 \%$ of the roof heat gain.

### 8.5.2 Computation of Cooling Loads

Now that the return air plenum temperatures are known, the office cooling load can be calculated. There are a few minor differences associated with treating the return air plenum separately:

- In Section 8.3, the area of the walls in the room included the side walls of the return air plenum. Now, as the plenum is being treated separately, the wall areas are those shown in Table 7.15, based on the room inside.
- The roof heat gains are replaced with the plenum heat gains in Table 8.27.
- Because 7 cfm of the infiltration was allocated to the plenum, the cfm in the room will be reduced by 7 cfm .

Table 8.27 Heat Gains Associated with the Return Air Plenum

| Hour | Heat Gain to Return Air, Btu/h | Heat Gain to Room from Plenum, Btu/h |
| :---: | :---: | :---: |
| 1 | -7 | -1 |
| 2 | -29 | -3 |
| 3 | -46 | -5 |
| 4 | -58 | -7 |
| 5 | -67 | -8 |
| 6 | -77 | -9 |
| 7 | -68 | -8 |

| 22 | 71 | 8 |
| 23 | 15 | 5 |
| 24 |  |  |
|  | -2 |  |
|  |  |  |

The differing cooling loads and total room sensible cooling loads are summarized in Table 8.28.

In addition, the sensible cooling load on the system is also calculated, as illustrated in Table 8.29 , by adding the zone sensible cooling load and the heat gain to the return air.

A comparison of the two approaches shows that the system sensible cooling loads are fairly similar but that the assumption that the return air plenum intercepts $30 \%$ of the roof heat gain tends to overpredict the cooling load in the room by about $10 \%$. The actual percentage of the roof heat gain that the return air plenum intercepts, for this case, is significantly higher.

### 8.6 Summary

This chapter has presented an in-depth example of the calculation of cooling loads for a single room. Loads with and without venetian blinds were calculated and two different approaches for treating the return air plenum were demonstrated. One aspect of load calculations that was not explored is the possibly counterintuitive dependence of the cooling load on the month. For some zones, peak cooling loads will occur at months that are not peak temperature months but rather that represent

peak solar heat gain conditions. In the northern hemisphere, the peak month would typically fall somewhere between July and December. A spreadsheet that automates much of the RTSM calculation, including the analysis of multiple months, is presented in Appendix B and included in the online supporting files accompanying this manual.

# Air Systems, Loads, IAQ, and Psychrometrics 

F
ollowing calculation of the cooling and heating loads, an analysis must be carried out to specify the various parameters for selection of equipment and design of the air distribution system. The psychrometric processes involved are rigorously discussed in Appendix A, where it is shown that the psychrometric chart is a useful tool in visualizing and solving problems.
The complete air-conditioning system may involve two or more of the processes considered in Appendix A. For example, in the conditioning of a space during the summer, the air supplied must have a sufficiently low temperature and moisture content to absorb the total cooling load of the space. Therefore, as the air flows through the space, it is heated and humidified. If the system is closed-loop, the air is then returned to the conditioning equipment, where it is cooled and dehumidified and supplied to the space again. Outdoor air usually is required in the space; therefore, outdoor air (makeup air) must be mixed with the return air (recirculated air) before it goes to the cooling and dehumidifying equipment. During the winter months, the same general processes occur but in reverse. Notice that the psychrometric analysis generally requires consideration of the outdoor air required, the recirculated air, and the space load. Various systems will be considered that carry out these conditioning processes, with some variations.

### 9.1 Classical Design Procedures

The most common design problem involves a system where outdoor air is mixed with recirculated air. The mixture is cooled and dehumidified and then delivered to the space, where it absorbs the load in the space and is returned to complete the cycle. Figure 9.1 shows a schematic of such a system, with typical operating conditions indicated. The sensible and latent cooling loads were calculated according to procedures discussed in Chapters 5-7, and the outdoor air quantity was derived from indoor air quality considerations. The system, as shown, is generic and represents several different types of systems when they are operating under full design load. Partial load conditions will be considered later. The primary objective of the analysis of the system is to determine the amount of air to be supplied to the space, its state, and the capacity and operating conditions for the coil. These results can then be used in designing the complete air distribution system.

## Example 9.1 <br> Cooling and Dehumidification Process

Analyze the system of Figure 9.1 to determine the quantity and state of the air supplied to the space and the required capacity and operating conditions for the cooling and dehumidifying equipment. The desired room conditions are given at state 3 (the states are the circled numbers in Figure 9.1). Assume sea-level elevation.

Solution: Rigorous solutions to the various processes are covered in Appendix A. An approach with minor approximations will be shown here. The given quantities are shown and the states are numbered for reference on ASHRAE Psychrometric Chart 1 (ASHRAE 1992) and shown schematically in Figure 9.2.

Losses in connecting ducts and fan power will be neglected. First, consider the steady flow process for the conditioned space. The room sensible heat factor (RSHF) is

$$
\text { RSHF }=\frac{42,000}{60,000}=0.7
$$

AIR CONDITIONING COMPANY

Figure 9.1 Cooling and dehumidifying system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.1).

Figure 9.2 Psychrometric processes for Example 9.1.
Source: Cooling and Heating Load Calculation Principles, Figure 8.2).
To provide the desired room conditions, the state of the air entering the space must lie on the line defined by state 3 and the RSHF on ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Therefore, state 3 is located as shown on Figure 9.2 and a line is drawn through the point parallel to the SHF $=0.7$ line on the protractor. State 2 may be any point on the line and is determined by the operating characteristics of the equipment, desired indoor air quality, and by what will be comfortable for the occupants. A typical leaving condition for the coil would be at a relative humidity of $85 \%$ to $90 \%$. The temperature $t_{2}$ is assumed to be $55^{\circ} \mathrm{F}$ and state 2 is determined. The air quantity required may now be found by considering processes 2-3 in Figure 9.2. Using Equation 9.1a,

$$
\begin{equation*}
q_{s}=60(\mathrm{cfm}) c_{p}\left(t_{3}-t_{2}\right) / v_{2} \tag{9.1a}
\end{equation*}
$$

where cfm represents the airflow rate in cfm and $q_{s}$ will be in $\mathrm{Btu} / \mathrm{h}$.
With $c_{p}$ assumed constant at $0.244 \mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{a}}{ }^{\circ} \mathrm{F}\right)$ from Appendix A, Equation 9.1a becomes

# Air Systems, Loads, IAQ, and Psychrometrics 

$$
\begin{equation*}
q_{s}=14.64(\mathrm{cfm})\left(t_{3}-t_{2}\right) / v_{2} \tag{9.1b}
\end{equation*}
$$

and further, when standard sea-level conditions are assumed, $v_{2}=13.28 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$,

$$
\begin{equation*}
q_{s}=1.1(\mathrm{cfm})\left(t_{3}-t_{2}\right) \tag{9.1c}
\end{equation*}
$$

Equation 9.1 c is used extensively to compute air quantities and sensible heat transfer, even though $v_{2}$ is not usually equal to the standard value, even at sea level. However, the assumption of sea-level pressure and elevation is reasonable up to about a 2500 ft elevation. At that point, the error in the computed volume flow rate (cfm) or sensible heat transfer will be about $10 \%$. The cfm will be about $10 \%$ low and sensible heat transfer will be about $10 \%$ high. The data for specific volume $v$ from a proper psychrometric chart or from Table A. 2 should be used for elevations above 2500 ft . To continue, $v_{2}=13.15 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$ from ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Using Equation 9.1b,

$$
\mathrm{cfm}_{2}=\frac{13.15(42,000)}{14.64(78-55)}=1640
$$

Using Equation 9.1c, $\mathrm{cfm}_{2}=1660$.
Attention is now directed to the cooling and dehumidifying unit. However, state 1 must be determined before continuing. A mass balance on the mixing section yields

$$
m_{a 0}+m_{a 4}=m_{a 1}=m_{a 2},
$$

but it is approximately true that

$$
\operatorname{cfm}_{0}+\operatorname{cfm}_{4}=\operatorname{cfm}_{1}=\mathrm{cfm}_{2}
$$

and

$$
\mathrm{cfm}_{4}=\mathrm{cfm}_{1}-\operatorname{cfm}_{0}=1640-500=1140
$$

and based on an energy balance, $t_{l}$ is given approximately by the following:

$$
\begin{gathered}
t_{1}=t_{0}\left(\frac{\mathrm{cfm}_{0}}{\mathrm{cfm}_{1}}\right)+t_{4}\left(\frac{\mathrm{cfm}_{4}}{\mathrm{cfm}_{1}}\right) \\
t_{1}=90\left(\frac{500}{1640}\right)+78\left(\frac{1140}{1640}\right)=82^{\circ} \mathrm{F}
\end{gathered}
$$

State 1 may now be located on line 3-0 of Figure 9.2 and ASHRAE Psychrometric Chart 1 (ASHRAE 1992). (Note that states 3, 4, and 5 all have the same conditions.) By using the graphical technique discussed in Appendix A, referring to Figure 9.2, and using cfm in place of mass flow rate, state 1 also may be found graphically:

$$
\begin{aligned}
& \frac{\overline{31}}{\overline{30}}=\frac{\operatorname{cfm}_{0}}{\operatorname{cfm}_{1}}=\frac{500}{1640}=0.30 \\
& \overline{31}=(0.3) \overline{30}
\end{aligned}
$$

State 1 is located at approximately $82^{\circ} \mathrm{F} \mathrm{dB}$ and $68^{\circ} \mathrm{F} \mathrm{wB}$. A line constructed from state 1 to state 2 on ASHRAE Psychrometric Chart 1 (ASHRAE 1992) then represents the process taking place in the conditioning equipment.

The coil may be specified in different ways, but the true volume flow rate entering the coil, $\mathrm{cfm}_{1}$, should be given. The mass flow rates $m_{a 1}$ and $m_{a 2}$ are the same; therefore, using Equation 9.2,

$$
\begin{equation*}
m_{a 1}=m_{a 2}=60\left(\frac{\mathrm{cfm}_{1}}{v_{1}}\right)=60\left(\frac{\mathrm{cfm}_{2}}{v_{2}}\right) \tag{9.2}
\end{equation*}
$$

or

$$
\begin{gathered}
\operatorname{cfm}_{1}=\operatorname{cfm}_{2} \frac{v_{1}}{v_{2}} \\
\operatorname{cfm}_{1}=1640 \frac{13.95}{13.15}=1740
\end{gathered}
$$

where $v_{2}$ is obtained from ASHRAE Psychrometric Chart 1 (ASHRAE 1992), Figure 9.2. Then the coil entering and leaving air conditions may be given as

$$
t_{1}=82^{\circ} \mathrm{F} \mathrm{~dB} \text { and } 68^{\circ} \mathrm{F} \mathrm{wB}
$$

and

$$
t_{2}=55^{\circ} \mathrm{F} \mathrm{~dB} \text { and } 53^{\circ} \mathrm{F} \mathrm{wB},
$$

and the coil capacity may be left as an exercise for the application engineer. However, it is recommended that the coil capacity also be determined from the following:

$$
\begin{gather*}
q_{c}=m_{a 1}\left(h_{1}-h_{2}\right)=\frac{60\left(\mathrm{cfm}_{1}\right)\left(h_{1}-h_{2}\right)}{v_{1}}  \tag{9.3}\\
q_{c}=\frac{851(57-32)}{0.865} \\
q_{c}=76,336 \mathrm{Btu} / \mathrm{h}
\end{gather*}
$$

The sensible heat factor for the cooling coil is found to be 0.64 using the protractor of ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Then

$$
q_{c s}=0.64(76,336)=48,855 \mathrm{Btu} / \mathrm{h}
$$

and

$$
q_{c l}=76,336-48,855=27,481 \mathrm{Btu} / \mathrm{h}
$$

Alternately, the sensible load on the coil could be computed from Equation 9.1a:

$$
\begin{aligned}
& q_{c s}=\frac{14.64\left(\mathrm{cfm}_{1}\right)\left(t_{1}-t_{2}\right)}{v_{1}} \\
& q_{c s}=\frac{14.64(1740)(82-55)}{13.95} \\
& q_{c s}=49,304 \mathrm{Btu} / \mathrm{h}
\end{aligned}
$$

and the latent load may then be determined by subtracting the sensible load from the coil load:

$$
q_{c l}=76,336-49,304=27,032 \mathrm{Btu} / \mathrm{h}
$$

The sum of $q_{c s}$ and $q_{c l}$, or $q_{c}$, is known as the coil refrigeration load (in contrast to the space cooling load). It is difficult to compute the coil latent load directly without the aid of a psychrometric chart or a computer routine. This problem is discussed further in Appendix A.

### 9.1.1 Fan Power

## Example 9.2 <br> Sensible Heat Gain

In an actual system, fans are required to move the air, and some energy from the fans is transferred to the air in the system. In addition, some heat may be lost or gained in the duct system. Referring to Figure 9.1, the supply fan is located just downstream of the cooling unit, and the return fan is upstream of the exhaust and mixing box. The temperature rise due to a fan is discussed in Appendix A, and data are given as a function of fan total efficiency and total pressure. At this point in the analysis, characteristics of the fan are unknown. However, an estimate can be made and checked later. Heat also may be gained in the supply and return ducts. The effect of the supply air fan and the heat gain to the supply air duct may be summed as shown on ASHRAE Psychrometric Chart 1 (ASHRAE 1992), Figure 9.3a, as process $1^{\prime}-2$. Likewise, heat is gained in the return duct from point 3 to point 4 , and the return fan temperature rise occurs between points 3 and 4, as shown in Figure 9.3 a . The condition line for the space, 2-3, is the same as it was before when the fans and heat gain were neglected. However, the requirements of the cooling coil have changed. Process 1-1' now shows that the capacity of the coil must be greater to offset the fan power input and duct heat gain.

Calculate the temperature rise of the air in a system like the one in Figure 9.1 and the effect on the system when the fan is a draw-through fan on the leaving side of the coil (Case A) and a blow-through fan behind the coil (Case B).

Solution: Assume the design total pressure difference across the fan is 2 in . of water, the fan efficiency is $75 \%$, and the motor efficiency is $85 \%$. For these conditions, Table A. 3 shows a temperature rise of the air of $1.0^{\circ} \mathrm{F}$ when the motor is outside the airstream. When the motor is in the airstream, the combined efficiency is $0.75 \cdot 0.85=0.64$. The temperature rise is then $1.1^{\circ} \mathrm{F}$. These temperature differences apply to both Case A and Case B. For

Case A, draw-through, state $1^{\prime}$ is located at $1^{\circ} \mathrm{F}$, or $1.1^{\circ} \mathrm{F}$ to the left of state 2 in Figure 9.3a. For Case B, blow-through, the state of the air entering the coil is located $1^{\circ} \mathrm{F}$ or $1.1^{\circ} \mathrm{F}$ to the right of state 1 in Figure 9.3a. Based on the solution of Example 9.1, the fan capacity is about 1600 cfm . The shaft power input would then be about 0.67 hp . First, considering the draw-through fan configuration (Case A), the process from the fan inlet to the point where the air has entered the space appears as process $1^{\prime}-2$ in Figure 9.3a. All of the power input to the fan has been transformed into stored energy, which is manifested in the temperature rise. All of the energy input is a load on the space. With the motor outside the airstream, the additional load on the space is

$$
q_{f}=0.67(2545)=1705 \mathrm{Btu} / \mathrm{h}
$$

With the motor in the airstream,

$$
q_{f}=\frac{0.67(2545)}{0.85}=2000 \mathrm{Btu} / \mathrm{h}
$$

where 1 hp is $2545 \mathrm{Btu} / \mathrm{h}$.
In the case of the blow-through fan configuration (Case B), the fan power is the same; however, the effect on the system is different. Most of the power results in a load on the coil, while a smaller part is a load on the space. It is customary to assign the entire load to the coil for simplicity. Figure 9.3 b shows the fan effect in this case as process $1-1^{\prime}$. The additional loads assigned to the coil are the same values computed above. It is apparent in both cases that the fan energy eventually appears as a coil load.

Air Systems, Loads, IAQ, and Psychrometrics

### 9.1.2 Ventilation for Indoor Air Quality

Indoor air quality (IAQ) is closely related to the psychrometric analysis leading to system design because air quality is largely dependent on the amount of outdoor air brought into the conditioned space, usually through the cooling and heating system. This is the purpose of the outdoor air introduced in Example 9.1 above. For typical occupied spaces, the amount of clean outdoor air is proportional to the number of people in the space. ANSI/ASHRAE Standard 62.1-2013, Ventilation for Acceptable Indoor Air Quality covers this subject and is the recognized source of data for purposes of system design. For full details, Standard 62.1 should be consulted. One approach specified in the standard is the ventilation rate procedure. With this approach, if the outdoor air is of acceptable quality, the minimum required amount of outdoor air per person and per square foot are specified in Table 6-1 of the standard. Table 9.1 is excerpted from Table 6.2.2.1 of the standard. The per-person and per-square-foot values are added together to determine the total required ventilation flow rate. If the actual number of occupants is not known, the default occupant density given in Table 9.1 may be used. Using this default occupancy, the combined outdoor air rate given on the right-hand side of the table is the per-person required ventilation flow rate. When the occupancy is known, this should be used instead of the estimated density.

## Example 9.3 Required Outdoor Air

An auditorium is designed for a maximum occupancy of 300 people and has a floor area of $2400 \mathrm{ft}^{2}$. Find the required outdoor airflow rate.

Solution: From Table 9.1 the minimum required outdoor airflow rate is

$$
\operatorname{cfm}_{m}=300(5)+2400(0.06)=1644
$$

The ventilation air rate necessary to offset the cooling or heating load will likely be greater than 4500 cfm . When the amount of air required to absorb the cooling load exceeds the minimum required ventilation air, it is generally desirable to recirculate and filter some of the air. Standard 62.1 gives full details for various conditions; a typical, somewhat idealized system will be presented here. A simple recirculating system is shown in Figure 9.4.

It is assumed that the ventilation system is a constant flow type, the outdoor air is acceptable by Table 9.1 standards, and ventilation effectiveness is $100 \%$. The recirculating rate is

$$
\operatorname{cfm}_{r}=\operatorname{cfm}_{v}-\operatorname{cfm}_{m},
$$

where $\mathrm{cfm}_{v}$ is the ventilation rate required by the cooling load or some factor other than air quality. It is assumed that the minimum amount of outdoor air based on occupancy will supply the needed oxygen and will sufficiently dilute the contaminants (including carbon dioxide) generated by the occupants and the building materials.

There also could be a case where the required outdoor air exceeds the amount of air needed to absorb the load. In this case, the condition of the air entering the space must be located on the space condition line (see Appendix A) to satisfy both requirements.

### 9.1.3 Cooling and Heating Coils

The heat transfer surfaces, usually referred to as coils and mentioned in Example 9.1, are of primary importance in an air-conditioning system. These surfaces are usually of a finned-tube geometry, where moist air flows over the finned surface and a liquid or two-phase refrigerant flows through the tubes. The coil generally will
have several rows of tubes in the airflow direction, and each row will be many tubes high and perpendicular to the airflow. Coil geometry will vary considerably depending on application. Steam and hot-water heating coils usually will have fewer rows of tubes (1-4), less dense fins ( $6-8$ fins per in.), and fewer circuits for fluid flow. Chilled-water and direct-expansion coils generally have more rows of tubes (4-8), more fins ( $8-14$ fins per in.), and more circuits for fluid flow on the tube side. It will be shown later that the coil must match the characteristics of the space and outdoor

Note: This table is an excerpt from Table 6.2.2.1 of ANSI/ASHRAE Standard 62.1-2013, Ventilation for Acceptable Indoor Air Quality. Please consult the standard for necessary details for application of this data.
air loads and that selection of the proper coil is fundamental to good system design. Catalogs from manufacturers, computer simulation programs, and databases are very useful in this regard.

Although the design engineer may seek help from an application engineer in selecting a coil, it is important that the nature of coil behavior and the control necessary for off-design conditions be understood.

## Heating Coils

Heating coils are much easier to design and specify than cooling coils because only sensible heat transfer is involved. The steam or water supplied to the coil usually must be controlled for partial-load conditions; thus, oversizing a coil, generally, is undesirable. Hot-water coils usually are preferable to steam coils, particularly when the load varies over a wide range. Steam and hot-water control is difficult when the flow rate must be reduced significantly.

## Cooling and Dehumidifying Coils

The design of cooling and dehumidifying coils is much more difficult because of the transfer of both sensible and latent heat. Further, the sensible and latent loads on a coil usually do not vary in a predictable way during off-design operation. It is entirely possible that a coil that performs perfectly under design conditions will be unsatisfactory under partial load. An understanding of the coil behavior may prevent such an occurrence.

Figure 9.5 shows a cooling and dehumidification process for a coil. The process is not actually a straight line, but when only the end points are of interest, a straight line is an adequate representation. The intersection of the process line with the saturation curve defines the apparatus dew-point temperature $t_{a d}$. This temperature is the approximate dew point of the surface where the cooling fluid is entering the coil and where the air is leaving, assuming counterflow of the fluids.

The apparatus dew point is useful in analyzing coil operation. For example, if the slope of process $1-2^{\prime}$ is so great that the extension of the process line does not intersect the saturation curve, the process probably is impossible to achieve with a coil in a single process and another approach will be necessary.

Process $1-2^{\prime}$ in Figure 9.5 is an example of such a process. The relative humidity of the air leaving a chilled-water coil is typically about $90 \%$ and, based on experience, it is approximately true that

$$
\begin{equation*}
t_{a d}=\left(\frac{t_{w}+t_{w b}}{2}\right) \tag{9.4a}
\end{equation*}
$$

Figure 9.4 Schematic of recirculating system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.4).
where $t_{w}$ is the entering water temperature and $t_{w b}$ is the wet-bulb temperature of the air leaving the coil. This approximation can be used to estimate the required water temperature for a cooling process:

$$
\begin{equation*}
t_{w} \approx 2 t_{a d}-t_{w b} \tag{9.4b}
\end{equation*}
$$

In so doing, a designer might avoid specifying a coil for an impossible situation or one that requires an abnormally low water temperature.

To maintain control of space conditions at partial-load conditions, the flow rate of the air or cooling fluid (water or brine solution) in the coil must be regulated. In a well-designed system, both probably are under control. It is interesting to note how the leaving air condition changes in each case. The processes shown in Figure 9.6 are for a typical chilled-water coil in an air-conditioning system. Process 1-2 is typical of the performance with full flow of air but greatly reduced flow of water, while process 1-3 is typical of performance with full flow of water but greatly reduced flow of air. To generalize, as water flow is reduced, the leaving air condition moves toward point 2 , and as airflow is reduced, the leaving air condition moves toward point 3. The conclusion is that by proper control of the flow rates of both fluids, a satisfactory air condition can be maintained under partial-load conditions.

# Air Systems, Loads, IAQ, and Psychrometrics 

## Bypass Factor

An alternate approach to the analysis of the cooling coil in Example 9.1 uses the so-called coil bypass factor. Note that when line 1-2 of Figure 9.5 is extended, it intersects the saturation curve at point d. This point represents the apparatus dewpoint temperature of the cooling coil. The coil cannot cool all of the air passing through it to the coil surface temperature. This fact makes the coil perform in a manner similar to what would happen if a portion of the air were brought to the coil temperature and the remainder bypassed the coil entirely. A dehumidifying coil thus produces unsaturated air at a higher temperature than the coil temperature. Again referring to Figure 9.5, notice that in terms of the length of line d-1, the length of line d-2 is proportional to the mass of air bypassed, and the length of line 1-2 is proportional to the mass of air not bypassed. Because line d-1 is inclined, it is approximately true that the fraction of air bypassed is

$$
\begin{equation*}
b=\left(\frac{t_{2}-t_{d}}{t_{1}-t_{d}}\right) \tag{9.5}
\end{equation*}
$$

and that

$$
\begin{equation*}
1-b=\left(\frac{t_{1}-t_{2}}{t_{1}-t_{d}}\right) \tag{9.6}
\end{equation*}
$$

The temperatures are dry-bulb values. Applying Equation 9.1b, the coil sensible load is

$$
\begin{equation*}
q_{s}=14.64\left(\operatorname{cfm}_{1}\right)\left(t_{1}-t_{d}\right)(1-b) / v_{1} \tag{9.7}
\end{equation*}
$$

## Example 9.4 Bypass Factor

Find the bypass factor for the coil of Example 9.1, and compute the sensible and latent heat transfer rates.

Solution: The apparatus dew-point temperature obtained from ASHRAE Psychrometric Chart 1 (ASHRAE 1992) as indicated in Figure 9.2 is $46^{\circ} \mathrm{F}$. Then from Equation 9.5 the bypass factor is

$$
b=\frac{(55-46)}{(82-46)}=0.25 \text { and } 1-b=0.75
$$

Equation 9.7 expresses the sensible heat transfer rate as

$$
q_{c s}=\frac{14.64(1740)(82-46)(0.75)}{13.95}=49,304 \mathrm{Btu} / \mathrm{h}
$$

The coil-sensible heat factor is used to compute the latent heat transfer rate. From Example 9.1, the SHF is 0.64 . The total heat transfer rate is

$$
q_{t}=\frac{q_{c s}}{\mathrm{SHF}}=\frac{49,304}{0.64}=77,038 \mathrm{Btu} / \mathrm{h}
$$

and

$$
q_{c l}=q_{t}-q_{c s}=77,038-49,304=27,734 \mathrm{Btu} / \mathrm{h}
$$

It should be noted that the bypass factor approach often results in errors compared to the approach of Example 9.1. Accurate data for bypass factors are not generally available.

## Load Calculation Applications Manual (I-P), Second Edition

Figure 9.7 Simple evaporative-cooling system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.7).

### 9.1.4 Hot and Dry Environment

In Example 9.1, the outdoor air was hot and humid. This is not always the case, and State 0 can be almost anywhere on ASHRAE Psychrometric Chart 1 (ASHRAE 1992). For example, the southwestern part of the United States is hot and dry during the summer, and evaporative cooling often can be used to an advantage under these conditions. A simple system of this type is shown schematically in Figure 9.7.

The dry outdoor air flows through an adiabatic spray chamber and is cooled and humidified. An energy balance on the spray chamber will show that the enthalpies $h_{o}$ and $h_{l}$ are equal (see Appendix A); therefore, the process $0-1$ is as shown in Figure 9.8.

Ideally, the cooling process terminates at the space condition line 1-2. The air then flows through the space and is exhausted. Large quantities of air are required, and this system is not satisfactory where the outdoor relative humidity is high. If the humidity ratio $W_{0}$ is too high, the process $0-1$ cannot intersect the condition line. For comfort air conditioning, evaporative cooling can be combined with a conventional system as shown in Figure 9.9.

When outdoor makeup air is mixed with recirculated air without evaporative cooling, the ideal result would be state 1 in Figure 9.10. The air would require only sensible cooling to state 2 on the condition line. Second, outdoor air could be cooled by evaporation to state $0^{\prime}$ in Figure 9.10 and then mixed with return air, resulting in state $1^{\prime}$. Sensible cooling would then be required from state $1^{\prime}$ to state 2. Finally, the outdoor air could ideally be evaporatively cooled all the way to state $1^{\prime \prime}$. This would require the least power for sensible cooling, but the air supplied to the space would be $100 \%$ outdoor air. It must be recognized that controlling the various processes above to achieve the desired results is difficult.

### 9.1.5 Space Heating

The contrasting problem of space air conditioning during the winter months may be solved in a manner similar to Example 9.1. Figure 9.11 shows a schematic of a heating system.

It usually is necessary to use a preheat coil to heat the outdoor air to a temperature above the dew point of the air in the equipment room so that condensation will not form on the air ducts upstream of the regular heating coil. Figure 9.12 shows the psychrometric processes involved. The heating and humidification process $1-1^{\prime}-2$, where the air is first heated from 1 to $1^{\prime}$, followed by an adiabatic humidification process from $1^{\prime}$ to 2 , is discussed in Appendix A.

(Source: Cooling and Heating Load Calculation Principles, Figure 9.12).

### 9.1.6 All Outdoor Air

There are situations where acceptable IAQ will require that all the ventilation air be outdoor air. Such a system would resemble Figure 9.13. Its psychrometric diagram could appear as shown in Figure 9.14. Outdoor air is cooled and dehumidified to state 1 when it enters the space, absorbs the cooling load, and is exhausted to the atmosphere. This system is analyzed in the same manner as Example 9.2 except there is no mixing of recirculated and outdoor air.

## Example 9.5 Coil Specification

A space has a total cooling load of $250,000 \mathrm{Btu} / \mathrm{h}$. The sensible portion of the load is $200,000 \mathrm{Btu} / \mathrm{h}$. The space condition is $78^{\circ} \mathrm{F} \mathrm{dB}$ and $50 \%$ relative humidity, and outdoor conditions are $95^{\circ} \mathrm{F} \mathrm{dB}$ and $75^{\circ} \mathrm{F}$ wB with standard sealevel pressure. IAQ considerations require $12,000 \mathrm{cfm}$ of outdoor air. Determine the amount of air to be supplied to the space, the condition of the supply air, and the coil specification.

AIR CONDITIONING COMPANY

Solution: The condition line is first constructed on ASHRAE Psychrometric Chart 1 (ASHRAE 1992) using the RSHF.

$$
\text { RSHF }=\frac{200,000}{250,000}=0.8
$$

The condition line appears as process 1-2 in Figure 9.14 and the extension of the line to the left. Point 1 is not known yet. Point 2 is the given space condition.

The quantity of outdoor air required is large and may be more than that required by the cooling load. Therefore, check to see what minimum amount of supply air will satisfy the cooling load. Assuming that a practical coil will cool air to about $90 \%$ relative humidity, this is given by recasting Equation 9.1 b as

$$
q_{2}=14.64(\mathrm{cfm})\left(t_{2}-t_{1}\right) / v_{1^{\prime}}
$$

or

$$
\mathrm{cfm}_{\min }=\frac{q_{2} v_{1}}{14.64\left(t_{2}-t_{1} \cdot\right)}=\frac{200,000(13.2)}{14.64(78-57)}=8587
$$

Figure 9.13 All-outdoor-air system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.13).

Figure 9.14 Psychrometric diagram of all-outdoor-air system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.14).

AIR CONDITIONING COMPANY
where the various properties are read from ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Obviously, the required outdoor air is greater than that required by the load. Therefore, point 1 in Figure 9.14 must be located to accommodate 12,000 cfmof outdoor air. Reconsider Equation 9.1 b and solve for $t_{1}$ :

$$
t_{1}=t_{2}-\frac{q_{2} v_{0}}{14.64(\mathrm{cfm})}
$$

The specific volume $v_{0}$ must be used because the amount of air to be supplied is based on $12,000 \mathrm{cfm}$ at outdoor conditions, $v_{0}=14.3 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$. Then,

$$
t_{1}=78-\frac{200,000(14.3)}{14.64(12,000)}=61.7^{\circ} \mathrm{F}
$$

Now, point 1 can be located on ASHRAE Psychrometric Chart 1 (ASHRAE 1992 ) and the entering air condition noted as about $62^{\circ} \mathrm{F}$ dB and $58^{\circ} \mathrm{F} w B$. The volume flow rate of air at state 1 will be

$$
\operatorname{cfm}_{1}=\operatorname{cfm}_{0}\left(\frac{v_{1}}{v_{0}}\right)=12,000\left(\frac{13.3}{14.3}\right)=11,160
$$

A line is now drawn from the outdoor condition at point 0 to point 1 , the entering air state. This line represents the coil cooling process. Using Equation 9.3,

$$
\begin{gathered}
q_{c}=60(\mathrm{cfm})\left(h_{o}-h_{1}\right) / v_{o} \\
q_{c}=\frac{60(12,000)}{14.3}(38.7-25.0)=689,790 \mathrm{Btu} / \mathrm{h}
\end{gathered}
$$

The use of all outdoor air more than doubles the refrigeration load compared to no outdoor air at all. Referring to ASHRAE Psychrometric Chart 1 (ASHRAE 1992), the coil sensible heat factor $(\mathrm{CSHF})=0.58$, and other operating parameters are the following:

| Entering Air: | $12,000 \mathrm{cfm}$ <br> standard sea-level pressure |
| :--- | :--- |
|  | $95^{\circ} \mathrm{F} \mathrm{dB}$ |
|  | $75^{\circ} \mathrm{F} \mathrm{wB}$ |
| Leaving Air: | $62^{\circ} \mathrm{F} \mathrm{dB}$ |
|  | $58^{\circ} \mathrm{F} \mathrm{wB}$ |

The coil sensible load could have been computed using Equation 9.1b and the total coil load then obtained using the CSHF.

### 9.2 Off-Design (Nonpeak) Conditions

The previous section treated the common space air-conditioning problem by assuming that the system was operating steadily at the design condition. Actually, the space requires only a part of the designed capacity of the conditioning equipment most of the time. A control system functions to match the required cooling or heating of the space to the conditioning equipment by varying one or more system parameters. For example, the quantity of air circulated through the coil and to the space may be varied in proportion to the space load, as in the variable-air-volume (VAV) system. Another

Air Systems, Loads, IAQ, and Psychrometrics
approach is to circulate a constant amount of air to the space but divert some of the return air around the coil and mix it with air coming off the coil to obtain a supply air temperature that is proportional to the space load. This is known as a face and bypass system. Another possibility is to vary the coil surface temperature with respect to the required load by changing the amount of heating or cooling fluid entering the coil. This technique usually is used in conjunction with VAV and face and bypass systems.

Figure 9.15a illustrates what might occur when the load on a VAV system decreases. The solid lines represent a full-load design condition, whereas the broken lines illustrate a part-load condition where the amount of air circulated to the space and across the coil has decreased. Note that the state of the outdoor air $0^{\prime}$ has changed and could be almost anyplace on the chart under part-load conditions. Because of the lower airflow rate through the coil, the air is cooled to a lower temperature and humidity. The room thermostat maintains the space temperature, but the humidity in the space may decrease. However, the process $2^{\prime}-3^{\prime}$ depends on the RSHF for the partial load. This explains why control of the water temperature or flow rate is desirable. Decreasing the water flow rate will cause point $2^{\prime}$ to move upward and to the right to a position where the room process curve may terminate nearer to point 3 .

The behavior of a constant-air-volume face and bypass system is shown in Figure 9.15b. The total design airflow rate is flowing at states 2, 3, and $3^{\prime}$, but a lower flow rate occurs at state $2^{\prime}$, leaving the coil. Air at states $2^{\prime}$ and $1^{\prime}$ is mixed downstream of the coil to obtain State 4. The total design flow rate and the enthalpy difference $h_{3}{ }^{\prime}-$ $h_{4}$ then match the space load. Note that the humidity at state 4 may be higher or lower than necessary, which makes state $3^{\prime}$ vary from the design value. At very small space loads, point 4 may be located very near state $1^{\prime}$ on the condition line. In this case, the humidity in the space may become high. This is a disadvantage of a multizone face and bypass system. Control of the coil water flow rate can help to correct this problem.

A constant-air-volume system with water flow rate control is shown in Figure 9.15 c. In this case, both the temperature and humidity of the air leaving the coil usually increase, and the room process curve $2^{\prime}-3^{\prime}$ may not terminate at state 3 . In most cases, state $3^{\prime}$ will lie above state 3 , causing an uncomfortable condition in the space. For this reason, water control alone usually is not used in commercial applications but is used in conjunction with VAV and face and bypass systems, as discussed previously. In fact, all water coils should have control of the water flow rate. This also is important to the operation of the water chiller and piping system. The following example illustrates the analysis of a VAV system with variable water flow.

Figure 9.15a Processes for off-design VAV system operation.
Source: Cooling and Heating Load Calculation Principles, Figure 8.15a).

AIR CONDITIONING COMPANY

Figure 9.15b Processes for off-design face and bypass system operation.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.15b).

Figure 9.15c Processes for off-design variable water flow system operation.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.15c).

## Example 9.6 <br> Coil for VAV System

A VAV system operates as shown in Figure 9.16. The solid lines show the full-load design condition of 100 tons with a room SHF of 0.75 . At the estimated minimum load of 15 tons with an SHF of 0.9 , the airflow rate is decreased to $20 \%$ of the design value and all outdoor air is shut off. Estimate the supply air and apparatus dew-point temperatures of the cooling coil for minimum load, assuming that state 3 does not change.

Solution: The solution is best carried out using ASHRAE Psychrometric Chart 1 (ASHRAE 1992), as shown in Figure 9.16. Because the outdoor air is off during the minimum load condition, the space condition and coil process lines will coincide as shown by line $3-2^{\prime}-\mathrm{d}^{\prime}$. This line is constructed by using the protractor of ASHRAE Psychrometric Chart 1 with an SHF of 0.9 . The apparatus dew point is seen to be $56^{\circ} \mathrm{F}$, compared with $51^{\circ} \mathrm{F}$ for the design condition. The airflow rate for the design condition is given by Equation 9.1b:

$$
\begin{gathered}
\mathrm{cfm}_{2}=\frac{q_{s} v_{2}}{14.64\left(t_{3}-t_{2}\right)} \\
\operatorname{cfm}_{2}=\frac{100(12,000)(0.75) 13.20}{14.64(78-56)}=36,885
\end{gathered}
$$

Then, the minimum volume flow rate is

$$
\mathrm{cfm}_{2}=0.2(36,885)=7377
$$

State point $2^{\prime}$ may then be determined by computing $t_{2}{ }^{\prime}$ :

$$
t_{2^{\prime}}=t_{3}-\frac{q_{s, \text { min }} v_{2}}{14.64\left(\mathrm{cfm}_{\min }\right)}=78-\frac{15(12,000) 0.9(13.3)}{14.64(7377)}=58^{\circ} \mathrm{F}
$$

where $v_{2}{ }^{\prime}$ is an estimated value.
Then from ASHRAE Psychrometric Chart 1 (ASHRAE 1992), at $58^{\circ} \mathrm{F} \mathrm{dB}$ and an SHF of 0.9 , point $2^{\prime}$ is located. The coil water temperatures may be estimated from Equation 9.4b. The entering water temperature would be increased from about $48^{\circ} \mathrm{F}$ to about $55^{\circ} \mathrm{F}$ from the design to the minimum load condition.

Figure 9.16 Psychrometric processes for Example 9.6.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.16).

### 9.2.1 Reheat System

Reheat was mentioned as a variation on the simple constant-flow and VAV systems to obtain control under part-load conditions. As noted previously, when the latent load is high, it may be impossible for a coil to cool the air to the desired condition. Figure 9.17 shows the psychrometric processes for a reheat system. After the air leaves the cooling coil at state 2 , it is then heated to state $2^{\prime}$ and enters the zone at state $2^{\prime}$ to accommodate the load condition. A VAV reheat system operates similarly.

Figure 9.17 Simple constant-flow system with reheat.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.17).

## Example 9.7

Reheat System

Suppose a space is to be maintained at $78^{\circ} \mathrm{F} \mathrm{dB}$ and $65^{\circ} \mathrm{F} \mathrm{wB}$ and requires air supplied at $60^{\circ} \mathrm{F} \mathrm{dB}$ and $55^{\circ} \mathrm{F} \mathrm{wB}$. The air entering the coil is at $85^{\circ} \mathrm{F} \mathrm{dB}$ and $70^{\circ} \mathrm{F} \mathrm{wB}$. Determine the quantity of air supplied to the space and the coil capacity and characteristics for a total space cooling load of $100,000 \mathrm{Btu} / \mathrm{h}$.

Solution: The coil entering air condition state 1 and the room conditioning process 2'-3 are located on ASHRAE Psychrometric Chart 1 (ASHRAE 1992) in Figure 9.18. Normally, a line would be drawn from point 1 to point $2^{\prime}$ for the coil process; however, note that when this is done as shown by the dashed line in Figure 9.18, the line does not intersect the saturation curve. This indicates that the process $1-2^{\prime}$ is either impossible or would require very cold water for the coil. Therefore, reheat is required. It would be reasonable for a coil to cool the air from point 1 to point 2 , where $W_{2^{\prime}}=W_{2}$ and $W_{2}=90 \%$. The air could then be heated (reheat) to point $2^{\prime}$, the necessary supply condition. The coil would require water at about $45^{\circ} \mathrm{F}$ to $46^{\circ} \mathrm{F}$. The required supply air to the space is given by Equation 9.1 b :

$$
q_{s}=\frac{14.64(\mathrm{cfm})\left(t_{3}-t_{2}\right)}{v_{2}^{\prime}}
$$

From ASHRAE Psychrometric Chart 1 (ASHRAE 1992), the RSHF is 0.64 ; then

$$
\operatorname{cfm}_{2}^{\prime}=\frac{q v_{2}^{\prime}(\mathrm{RSHF})}{14.64\left(t_{3}-t_{2}\right)}=\frac{100,000(13.25) 0.64}{14.64(78-60)}=3218
$$

The coil capacity is

$$
\begin{equation*}
q_{c}=\frac{60\left(\mathrm{cfm}_{1}\right)\left(h_{1}-h_{2}\right)}{v_{1}} \tag{9.8}
\end{equation*}
$$

where $\operatorname{cfm}_{1}=\operatorname{cfm}_{2}^{\prime} \frac{v_{1}}{v_{2}^{\prime}}$.

Figure 9.18 Psychrometric processes for Example 9.7.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.18).

Figure 9.19 Psychrometric processes for Example 9.8.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.19).

The volume flow rate of air entering the coil is from above:

$$
\mathrm{cfm}_{1}=3218 \frac{14.0}{13.25}=3400
$$

with air entering at $85^{\circ} \mathrm{F} \mathrm{dB}$ and $70^{\circ} \mathrm{F} \mathrm{wB}$ and air leaving at $54^{\circ} \mathrm{F} \mathrm{dB}$ and $52^{\circ} \mathrm{F}$ wB. The reheat coil has a capacity of

$$
q_{r}=\frac{14.64\left(\mathrm{cfm}_{2}^{\prime}\right)\left(t_{2}^{\prime}-t_{2}\right)}{v_{2}^{\prime}}=\frac{14.64(3218)(60-54)}{13.25}=21,334 \mathrm{Btu} / \mathrm{h}
$$

The following example relates to coil bypass control.

## Load Calculation Applications Manual (I-P), Second Edition

Example 9.8
Coil Bypass

A space is conditioned by a multizone unit using bypass control. The design operating condition for the space is shown in Figure 9.19 by process 2-3, where $t_{3}$ is thermostatically controlled at $75^{\circ} \mathrm{F} \mathrm{dB}$.

Consider a part-load condition where the space cooling load is one-third the design value with an RSHF of 0.9 . Assume that the coil will operate with the same apparatus dew point as the design condition and the air will enter the coil at $75^{\circ} \mathrm{F} \mathrm{dB}$ with the same humidity ratio as the design condition. The air leaving the coil will have a relative humidity of about $90 \%$. Find the space condition and the coil bypass ratio.

Solution: The design operating condition is shown in Figure 9.19. These processes and the partial load coil process $1^{\prime}-2^{\prime}$ are then drawn on ASHRAE Psychrometric Chart 1 (ASHRAE 1992). The partial load condition line $2^{\prime \prime}-3^{\prime}$ is not known at this point, but point $3^{\prime}$ will lie on the $75^{\circ} \mathrm{F} \mathrm{dB}$ temperature line and point $2^{\prime \prime}$ will lie on process line $1^{\prime}-2^{\prime}$. The design load is given by

$$
q=m_{2}\left(h_{3}-h_{2}\right)
$$

and the partial load is

$$
q_{0}=\frac{m_{2}\left(h_{3}-h_{2}\right)}{3}
$$

Also, the partial sensible load is given by

$$
q_{s 0}=(\mathrm{RSHF}) q_{0}=m_{2} c_{p}\left(t_{3}^{\prime}-t_{2}^{\prime \prime}\right)
$$

Then substituting for $q_{0}$ and noting that $t_{3}^{\prime}=t_{3}$.

$$
\begin{aligned}
t_{2}^{\prime \prime} & =t_{3}-\frac{(\mathrm{RSHF})\left(h_{3}-h_{2}\right)}{3 c_{p}} \\
t_{2}^{\prime \prime} & =75-\frac{0.9(28-21.8)}{3(0.244)}=67.4^{\circ} \mathrm{F} \mathrm{~dB}
\end{aligned}
$$

Process $2^{\prime \prime}-3^{\prime}$ can now be drawn on ASHRAE Psychrometric Chart 1 (ASHRAE 1992). The space condition is given by point $3^{\prime}$ as $75^{\circ} \mathrm{F} \mathrm{dB}$ and $65^{\circ} \mathrm{F}$ wB with a relative humidity of $59 \%$. Note that this may be an uncomfortable condition for occupants; however, there is no practical way to avoid this with bypass control. The bypass ratio is

$$
\mathrm{BR}=\frac{\text { Amount of air bypassed at state } 1^{\prime}}{\text { Amount of air cooled at state } 2^{\prime}}
$$

Because adiabatic mixing is occurring, the ratio is given by the length of the line segments from ASHRAE Psychrometric Chart 1 (ASHRAE 1992):

$$
\mathrm{BR}=\frac{\overline{2^{\prime}-2^{\prime \prime}}}{\overline{2^{\prime}-1^{\prime}}}=0.6
$$

The purpose of a dual-duct system is to adjust to highly variable conditions from zone to zone and to give accurate control. Figure 9.20 offers a schematic of such a system, showing one typical zone, and Figure 9.21 shows the processes on

# Air Systems, Loads, IAQ, and Psychrometrics 

ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Part of the air is cooled to state 2 and part of the air is heated to state 3 . A thermostat controls dampers in the terminal unit to mix the air at states 2 and 3 in the correct proportion, resulting in the mixed air being at state 4 , which is supplied to the zone. Process $4-5$ is the condition line for the zone. The flow rates of the two airstreams also may vary, as with regular VAV.

The economizer cycle is a system used during part-load conditions when outdoor temperature and humidity are favorable to saving operating energy. One must be cautious in the application of such a system, however, if the desired space conditions are to be maintained. Once the cooling equipment, especially the coil, has been selected, there are limitations on the quantity and state of the outdoor air. The coil apparatus dew point can be used as a guide to avoid impossible situations. For example, a system is designed to operate as shown by the solid process lines in Fig-

Figure 9.20 Schematic of dual-duct system.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.20).

Figure 9.21 Psychrometric processes for dualduct system of Figure 9.20.

## Load Calculation Applications Manual (I-P), Second Edition

Figure 9.22 Psychrometric processes for economizer cycle.
(Source: Cooling and Heating Load Calculation Principles, Figure 8.22).
ure 9.22. Assume that the condition line 2-3 does not change, but state 0 changes to state $0^{\prime}$. Theoretically, a mixed state $1^{\prime}$ located anyplace on line $0^{\prime}-3$ could occur, but the air must be cooled and dehumidified to state 2 . To do this, the coil apparatus dew point must be reasonable. Values below about $48^{\circ} \mathrm{F}$ are not economical to attain. Therefore, state $1^{\prime}$ must be controlled to accommodate the coil. It can be seen in Figure 9.22 that moving state $1^{\prime}$ closer to state $0^{\prime}$ lowers the coil apparatus dew point rapidly and it soon reaches the condition where the coil process line will not intersect the saturation curve, indicating an impossible condition. It is obvious in Figure 9.22 that less energy is required to cool the air from state $1^{\prime}$ to 2 than from state 1 to 2 . There are many other possibilities that must be analyzed on their own merits. Some may require more or less outdoor air, humidification, or reheat to reach state 2 .

Heating Load Calculations

Before a heating system is designed, the maximum probable heat loss from each room or space to be heated must be estimated. There are three kinds of heat losses: (1) heat transmitted through walls, ceiling, floor, glass, or other surfaces; (2) heat required to warm outdoor air entering the space; and (3) the heat needed to warm or thaw significant quantities of materials brought into the space.

The actual heat loss problem is transient because the outdoor temperature, wind velocity, and sunlight are constantly changing. During the coldest months, however, sustained periods of very cold, cloudy, and stormy weather with relatively small variation in outdoor temperature may occur. In this situation, heat loss from the space will be relatively constant and, in the absence of internal heat gains, will peak during the early morning hours. Therefore, for design purposes, the heat loss usually is estimated based on steady-state heat transfer for some reasonable design temperature. Transient analyses often are used to study the actual energy requirements of a structure in simulation studies. In such cases, solar effects and internal heat gains are taken into account.

The practice of temperature setback has become a relatively common method of saving on heating energy costs. This control strategy causes a transient variation in the room temperature that may have an effect on the peak heating load and the comfort of the occupants. Such calculations should be done using the heat balance procedure described in Chapter 11.

In this chapter, two options for performing a steady-state heating load calculation are described:

1. It can be done with a cooling load calculation procedure, if the right assumptions are applied (Section 10.1).
2. It can be done as a separate, stand-alone steady-state calculation in a spreadsheet or by hand (the classic heat loss calculation described in Section 10.2).

### 10.1 Heating Load Using Cooling Load Calculation Procedures

In theory, any cooling load calculation procedure can also be used to calculate heating loads. It is simply a matter of differing assumptions. For heating load calculations, the differences are as follows:

1. There is no solar input, as the peak heating load is assumed to occur at night. If a dedicated cooling load calculation computer program is used, it may have an option that turns off the solar input. If not, it may be possible to turn off the solar input by setting the clearness to zero.
2. It is generally assumed that there are no internal heat gains (e.g., people, lights, equipment), and these may be set to zero by the user.
3. Constant outdoor temperatures are assumed; this may be done by setting the daily range to zero.
4. In cooling load calculations, it is often assumed that there is no net heat transfer to or from the ground via foundation elements. For heating load calculations, these losses should be included in the calculation. Calculation procedures are described in Section 10.2.

## Load Calculation Applications Manual (I-P), Second Edition

### 10.2 Classic Heat Loss Calculations

The general procedure for calculation of design heat losses of a structure is as follows:

1. Select the outdoor design conditions: temperature, humidity, and wind direction and speed (Chapter 4).
2. Select the indoor design conditions to be maintained (Chapter 4).
3. Estimate the temperature in any adjacent unheated spaces.
4. Select the transmission coefficients (Chapter 3) and compute the heat losses for walls, floors, ceilings, windows, doors, and foundation elements.
5. Compute the heat load caused by infiltration and any other outdoor air introduced directly to the space (Chapter 5).
6. Find the sum of the losses due to transmission and infiltration.

### 10.2.1 Outdoor Design Conditions

The ideal heating system would provide enough heat to match the heat loss from the structure. However, weather conditions vary considerably from year to year, and heating systems designed for the worst weather conditions on record would have a great excess of capacity most of the time. The failure of a system to maintain design conditions during brief periods of severe weather usually is not critical. However, close regulation of indoor temperature may be critical for some occupancies or industrial processes. Design temperature data are provided in Chapter 4, along with a discussion of the application of these data. Generally, it is recommended that the $99 \%$ temperature values given in the tabulated weather data be used. However, caution should be exercised and local conditions always investigated. In some locations, outdoor temperatures are commonly much lower and wind velocities higher than those given in the tabulated weather data.

### 10.2.2 Indoor Design Conditions

The main purpose of the heating system is to maintain indoor conditions that make most of the occupants comfortable. It should be kept in mind, however, that the purpose of heating load calculations is to obtain data for sizing the heating system components. In many cases, the system will rarely be called upon to operate at the design conditions. Therefore, the use and occupancy of the space is a general consideration from the design temperature point of view. Later, when the energy requirements of the building are computed, the actual conditions in the space and outdoor environment, including internal heat gains, must be considered.

The indoor design temperature should be selected at the lower end of the acceptable temperature range so that the heating equipment will not be oversized. Even properly sized equipment operates under partial load at reduced efficiency most of the time. Therefore, any oversizing aggravates this condition and lowers the overall system efficiency. A maximum design dry-bulb temperature of $70^{\circ} \mathrm{F}$ is recommended for most occupancies. The indoor design value of relative humidity should be compatible with a healthful environment and the thermal and moisture integrity of the building envelope. A maximum relative humidity of $30 \%$ is recommended for most situations.

### 10.2.3 Calculation of Transmission Heat Losses

## Exterior Surface Above Grade

All above-grade surfaces exposed to outdoor conditions (e.g., walls, doors, ceilings, fenestration, and raised floors) are treated identically, as follows:

$$
\begin{align*}
& q=A \cdot H F  \tag{10.1}\\
& H F=U \Delta t \tag{10.2}
\end{align*}
$$

where $H F$ is the heating load factor in $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$.

## Below-Grade Surfaces

An approximate method for estimating below-grade heat loss (based on the work of Latta and Boileau [1969]) assumes that the heat flow paths shown in Figure 10.1 can be used to find the steady-state heat loss to the ground surface, as follows:

$$
\begin{equation*}
H F=U_{a v g}\left(t_{i n}-t_{g r}\right) \tag{10.3}
\end{equation*}
$$

where
$U_{\text {avg }}=$ average U-factor for below-grade surface, Btu $/ \mathrm{h} \cdot \mathrm{ft}{ }^{2} \cdot{ }^{\circ} \mathrm{F}$, from Equation 10.5 or 10.6
$t_{\text {in }} \quad=$ below-grade space air temperature, ${ }^{\circ} \mathrm{F}$
$t_{g r} \quad=$ design ground surface temperature, ${ }^{\circ} \mathrm{F}$, from Equation 10.4
The effect of soil heat capacity means that none of the usual external design air temperatures are suitable values for $t_{g r}$. Ground surface temperature fluctuates about an annual mean value by amplitude $A$, which varies with geographic location and surface cover. The minimum ground surface temperature, suitable for heat loss estimates, is therefore

$$
\begin{equation*}
t_{g r}=\bar{t}_{g r}-A \tag{10.4}
\end{equation*}
$$

where
$\bar{t}_{g r}=$ mean ground temperature, ${ }^{\circ} \mathrm{F}$, estimated from the annual average air temperature or from well-water temperatures, shown in Figure 17 of Chapter 34 in the ASHRAE Handbook—HVAC Applications (2011)
$A=$ ground-surface temperature amplitude, ${ }^{\circ} \mathrm{F}$, from Figure 10.2 for North America

Figure 10.1 Heat flow from below-grade surfaces.
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 18, Figure 12).

Figure 10.2 Ground temperature amplitudes for North America.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Figure 13).

Figure 10.3 Below-grade depth parameters.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Figure 14).

Figure 10.3 shows depth parameters used in determining $U_{\text {avg }}$. For walls, the region defined by $z_{1}$ and $z_{2}$ may be the entire wall or any portion of it, allowing partially insulated configurations to be analyzed piecewise.

The below-grade wall average U-factor is given by

$$
\begin{equation*}
U_{\text {avg, } b w}=\frac{2 k_{\text {soil }}}{\pi\left(z_{2}-z_{1}\right)} \cdot\left[\ln \left(z_{2}+\frac{2 k_{\text {soil }} R_{\text {other }}}{\pi}\right)-\ln \left(z_{1}+\frac{2 k_{\text {soil }} R_{\text {other }}}{\pi}\right)\right] \tag{10.5}
\end{equation*}
$$

where
$U_{a v g, b w}=$ average U-factor for wall region defined by $z_{1}$ and $z_{2}, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$k_{\text {soil }}=$ soil thermal conductivity, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$
$R_{\text {other }}=$ total resistance of wall, insulation, and inside surface resistance, $\mathrm{h} \cdot \mathrm{ft}^{2}{ }^{\circ} \mathrm{F} / \mathrm{Btu}$
$z_{1}, z_{2}=$ depths of top and bottom of wall segment under consideration, ft (see Figure 10.3)

The value of the soil thermal conductivity $k$ varies widely with soil type and moisture content. A typical value of $0.8 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$ has been used previously to tabulate U-factors, and $R_{\text {other }}$ is approximately $1.47 \mathrm{~h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F} / \mathrm{B}$ tu for uninsulated concrete walls. For these parameters, representative values for $U_{a v g, b w}$ are shown in Table 10.1.

The average below-grade floor U-factor (where the entire basement floor is uninsulated or has uniform insulation) is given by

$$
\begin{equation*}
U_{\text {avg, bf }}=\frac{2 k_{\text {soil }}}{\pi w_{b}} \cdot\left[\ln \left(\frac{w_{b}}{2}+\frac{z_{f}}{2}+\frac{k_{\text {soil }} R_{\text {other }}}{\pi}\right)-\ln \left(\frac{z_{f}}{2}+\frac{k_{\text {soil }} R_{\text {other }}}{\pi}\right)\right] \tag{10.6}
\end{equation*}
$$

where
$w_{b}=$ basement width (shortest dimension), ft
$\mathrm{z}_{\mathrm{f}}=$ floor depth below grade, ft (see Figure 10.3)
Representative values of $U_{\text {avg,bf }}$ for uninsulated basement floors are shown in Table 10.2.

## At-Grade Surfaces

Concrete slab floors may be (1) unheated, relying for warmth on heat delivered above floor level by the heating system, or (2) heated, containing heated pipes or

Table 10.1 Average U-Factors for Basement Walls with Uniform Insulation

| 7 | 0.032 | 0.030 | 0.028 | 0.026 |

Soil conductivity is $0.8 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$; floor is uninsulated. For other soil conductivities and insulation, use Equation 10.5 .

## Load Calculation Applications Manual (I-P), Second Edition

ducts that constitute a radiant slab or portion of it for complete or partial heating of the building.

The simplified approach that treats heat loss as proportional to slab perimeter allows slab heat loss to be estimated for both unheated and heated slab floors:

$$
\begin{align*}
& q=p \cdot H F  \tag{10.7}\\
& H F=F_{p} \Delta t \tag{10.8}
\end{align*}
$$

where
$q=$ heat loss through perimeter, Btu/h
$F_{p}=$ heat loss coefficient per foot of perimeter, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$ (Table 10.3)
$p=$ perimeter (exposed edge) of floor, ft

## Surfaces Adjacent to Buffer Space

Heat loss to adjacent unconditioned or semiconditioned spaces can be calculated using a heating factor based on the partition temperature difference:

$$
\begin{equation*}
H F=U\left(t_{i n}-t_{b}\right) \tag{10.9}
\end{equation*}
$$

### 10.2.4 Infiltration

All structures have some air leakage or infiltration. This means heat loss will occur because the cold, dry outdoor air must be heated to the inside design temperature and moisture must be added to increase the humidity to the design value. Procedures for estimating the infiltration rate are discussed in Chapter 5.

Once the infiltration rate has been calculated, the resulting sensible heat loss, equivalent to the sensible heating load due to infiltration, is given by

$$
\begin{equation*}
q_{s}=60(\mathrm{cfm} / v) c_{p}\left(t_{i n}-t_{o}\right) \tag{10.10}
\end{equation*}
$$

where
$\mathrm{cfm}=$ volume flow rate of the infiltrating air, $\mathrm{ft}^{3} / \mathrm{min}$
$c_{p} \quad=$ specific heat capacity of the air, Btu/(lbm $\left.\cdot{ }^{\circ} \mathrm{F}\right)$
$v \quad=$ specific volume of the infiltrating air, $\mathrm{ft}^{3} / \mathrm{lbm}$

Table 10.3 Heat Loss Coefficient $F_{p}$ of Slab Floor Construction
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 18, Table 24)

| Construction | Insulation | $\boldsymbol{F}_{\boldsymbol{p}}, \mathbf{B t u} \mathbf{h} \cdot \mathbf{f f} \cdot{ }^{\circ} \mathbf{F}$ |
| :---: | :---: | :---: |
| 8 in. block wall, brick facing | Uninsulated | 0.68 |
|  | $\mathrm{R}-5.4$ from edge to footer | 0.50 |
| 4 in. block wall, brick facing | Uninsulated | 0.84 |
|  | R-5.4 from edge to footer | 0.49 |
| Metal stud wall, stucco | Uninsulated | 1.20 |
|  | R-5.4 from edge to footer | 0.53 |
| Poured concrete wall with | Uninsulated | 2.12 |
| duct near perimeter* | R-5.4 from edge to footer | 0.72 |

[^11]Assuming standard air conditions ( $59^{\circ} \mathrm{F}$ and sea-level conditions) for $v$ and $c_{p}$, Equation 10.10 may be written as

$$
\begin{equation*}
q_{s}=1.10(\mathrm{cfm})\left(t_{i n}-t_{o}\right) \tag{10.11}
\end{equation*}
$$

The infiltrating air also introduces a latent heating load given by

$$
\begin{equation*}
q_{l}=60(\mathrm{cfm} / v)\left(W_{i n}-W_{o}\right) D_{h} \tag{10.12}
\end{equation*}
$$

where
$W_{\text {in }}=$ humidity ratio for the inside space air, $\mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$ $W_{o}=$ humidity ratio for the outdoor air, $\mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$
$D_{h}=$ change in enthalpy to convert $1 \mathrm{lb}_{\mathrm{w}}$ from vapor to liquid, Btu/lb $\mathrm{b}_{\mathrm{w}}$
For standard air and nominal indoor comfort conditions $\left(59^{\circ} \mathrm{F}\right.$ and $72^{\circ} \mathrm{F}$, respectively), the latent load may be expressed as

$$
\begin{equation*}
q_{l}=4840(\mathrm{cfm})\left(W_{i n}-W_{o}\right) \tag{10.13}
\end{equation*}
$$

The coefficients 1.10 in Equation 10.11 and 4840 in Equation 10.13 are given for standard conditions. They actually depend on temperature and altitude (and, consequently, pressure). Appendix A gives formulations based on temperature and altitude.

### 10.2.5 Heat Losses in the Air Distribution System

The losses of a duct system must be considered when the ducts are not in the conditioned space. Proper insulation will reduce these losses but cannot completely eliminate them. The losses may be estimated using the following relation:

$$
\begin{equation*}
q=U A_{s} D t_{m} \tag{10.14}
\end{equation*}
$$

where
$U=$ overall heat transfer coefficient, $\mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$
$A=$ outside surface area of the duct, $\mathrm{ft}^{2}$
$D t_{m}=$ mean temperature difference between air in the duct and the environment, ${ }^{\circ} \mathrm{F}$
When the duct is covered with 1 or 2 in . of insulation that has a reflective covering, the heat loss usually will be reduced sufficiently to assume that the mean temperature difference is equal to the difference in temperature between the supply air temperature and the environmental temperature. Unusually long ducts should not be treated in this manner, and a mean air temperature should be used instead.

It is common practice to estimate heat loss or gain to air ducts by simply assuming a small percentage of the sensible load. For well-insulated ducts, a $2 \%$ to $5 \%$ loss would be reasonable. It should be noted that heat loss from the supply air ducts represents a load on the space, while heat loss from the return air ducts represents a load on the heating equipment.

### 10.2.6 Auxiliary Heat Sources

The heat energy supplied by people, lights, motors, and machinery should always be estimated, but any actual allowance for these heat sources requires careful consideration. People may not occupy certain spaces in the evenings, on weekends, and during other periods, and these spaces generally must be heated to a reasonably comfortable temperature prior to occupancy. Therefore, it is customary to ignore internal heat gain in the heating load calculation for most spaces. Heat sources in

## Load Calculation Applications Manual (I-P), Second Edition

industrial plants, if available during occupancy, should be substituted for part of the heating requirement. In fact, there are situations where so much heat energy is available that outdoor air must be used to prevent overheating of the space. However, sufficient heating equipment must still be provided to prevent freezing or other damage during periods when a facility is shut down.

### 10.3 Heating Load Calculation Example

This section gives a start-to-finish example of calculating the heating load for a single room. Rather than starting from building plans, determining U-factors, etc., we will compute the heating load for the office used as an example in Chapters 7 and 8 , where there was a full discussion of issues such as determination of U-factors, areas, etc. That office is on the second floor. Since heat losses through foundation elements are often important for heating loads, we will consider the room both as a second-story room and as if it were moved to the first story and the existing floor was replaced with a slab-on-grade floor.

### 10.3.1 Room Description and Design Conditions

A more detailed description of the room can be found in Chapter 8; the description here extracts the relevant information from that chapter. Table 10.4 summarizes the exterior surfaces of the room. (Note that for the steady-state heating load calculation, the interior surfaces do not store and discharge heat, so they may be ignored for the calculation.) As described in Chapter 8, the walls and roof assumed an exterior surface conductance of $4 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$. As shown in Table 3.4, this is consistent with summer design conditions. For winter, a value of $6 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F}$ was taken. This value was used to compute the U-factors for the opaque surfaces. For the windows, the calculated value of $0.32 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F}$ was used.

Selection of design conditions depends on the application; here the $99 \%$ annual heating design condition, $26.4^{\circ} \mathrm{F}$, will be used as the outdoor condition and $70^{\circ} \mathrm{F}$ will be used as the indoor condition. This gives a $\Delta t$ of $43.6^{\circ} \mathrm{F}$. For purposes of estimating latent heat losses, desired indoor conditions are chosen at $50 \%$ relative humidity. For outdoor conditions, the $99 \%$ outdoor humidity condition 9.1 grains of water vapor per pound of dry air will be used. Infiltration of 20 cfm based on 1 ach is assumed for this example.

### 10.3.2 Heating Load without Floor Losses

For the first part of this example, with the office located on the second floor and conditioned office space below, there is no net heat loss from the floor. In this case, the heating load is composed of heat losses from exterior, above-grade surfaces and

Table 10.4 Exterior Surfaces

| Surface Name | Area, <br> $\mathbf{f t}^{2}$ | $\mathbf{U}$, <br> $\left(\mathbf{B t u} / \mathbf{h} \cdot \mathbf{f t}^{\mathbf{2} \cdot}{ }^{\mathbf{F}}\right)$ |
| :---: | :---: | :---: |
| Southeast brick | 61 | 0.055 |
| Southeast spandrel | 16 | 0.068 |
| Southeast window | 40 | 0.33 |
| Southwest brick | 34 | 0.055 |
| Southwest spandrel | 16 | 0.068 |
| Southwest window | 40 | 0.33 |
| Roof | 130 | 0.032 |

infiltration. The heat losses from exterior, above-grade surfaces are determined with the heating factors defined in Section 10.2.3. Heating factors are computed with Equation 10.2 by multiplying the U-factors by the $\Delta t$ of $43.6^{\circ} \mathrm{F}$. The resulting heating factors are given in Table 10.5. The heat losses from each surface are then determined with Equation 10.1 and given in the last column of Table 10.5.

The sensible infiltration heat loss may be computed using Equation 10.11:

$$
q_{s}=1.10(20 \mathrm{cfm})\left(70^{\circ} \mathrm{F}-26.4^{\circ} \mathrm{F}\right)=959 \mathrm{Btu} / \mathrm{h}
$$

To compute latent infiltration heat loss from Equation 10.13, the indoor and outdoor humidity ratios must be determined. The indoor humidity was given as $50 \%$ relative humidity at $70^{\circ} \mathrm{F}$. From the psychrometric chart, this is about $0.0078 \mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$. The exterior humidity ratio was given as 9.1 grains of water vapor per pound of dry air. With 7000 grains per pound, this is equivalent to $0.0013 \mathrm{lb}_{\mathrm{w}} / \mathrm{lb}_{\mathrm{a}}$. The latent infiltration heat loss may be computed using Equation 10.13:

$$
q_{l}=4840(20 \mathrm{cfm})(0.0078-0.0013)=629 \mathrm{Btu} / \mathrm{h}
$$

Totaling all of the heat losses, the total sensible heating load is $1650+959=$ $2609 \mathrm{Btu} / \mathrm{h}$. The total latent heating load is $629 \mathrm{Btu} / \mathrm{h}$.

### 10.3.3 Heating Load with Slab-on-Grade Floor Losses

If the office is moved to the ground floor (while retaining its roof), the heating load would simply be increased by the heat loss through the slab-on-grade floor. The calculation procedure is described in Section 10.2.3 and requires the use of Equations 10.7 and 10.8 . The exposed perimeter $p$ of the office is the sum of the lengths of the southeast and southwest walls, or 23 ft . The heat loss coefficient can be estimated using Table 10.3. The spandrel/brick wall construction does not obviously fit into any of the categories in Table 10.3. But given the range of constructions, a worse case might be the metal stud wall/stucco construction with an $F_{p}$ of 1.2 Btu/h $\cdot f t \cdot{ }^{\circ} \mathrm{F}$. Then, from Equation 10.8 , the heating factor for the slab-on-grade floor is

$$
H F=1.2 \mathrm{Btu} / \mathrm{h} \cdot{ }^{\circ} \mathrm{F} \cdot 43.6^{\circ} \mathrm{F}=52.3 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}
$$

and the heat loss from Equation 10.7 is

$$
q=23 \cdot 52.3=1203 \mathrm{Btu} / \mathrm{h}
$$

Table 10.5 Exterior, Above-Grade Surface Heat Losses

| Surface | $\mathbf{A r e a}_{\mathbf{\prime}} \mathbf{f t}^{\mathbf{2}}$ | $\boldsymbol{U}, \mathbf{B t u} \cdot \mathbf{h} \cdot \mathbf{f t}^{\mathbf{2} \cdot} \mathbf{} \mathbf{F}$ | $\boldsymbol{H F}, \mathbf{B t u} / \mathbf{h} \cdot \mathbf{f t}^{\mathbf{2}}$ | $\boldsymbol{q}, \mathbf{B t u} \mathbf{h}$ |
| :---: | :---: | :---: | :---: | :---: |
| Southeast brick | 61 | 0.055 | 2.4 | 147 |
| Southeast spandrel | 16 | 0.068 | 3.0 | 48 |
| Southeast window | 40 | 0.33 | 14.3 | 573 |
| Southwest brick | 34 | 0.055 | 2.4 | 82 |
| Southwest spandrel | 16 | 0.068 | 3.0 | 48 |
| Southwest window | 40 | 0.33 | 14.3 | 573 |
| Roof | 130 | 0.032 | 1.4 | 180 |
| Total | - | - | - | 1650 |

## Load Calculation Applications Manual (I-P), Second Edition

So, with the slab-on-grade floor, totaling all of the heat losses, the total sensible heating load is $1650+959+1203=3812 \mathrm{Btu} / \mathrm{h}$. The total latent heating load remains $629 \mathrm{Btu} / \mathrm{h}$.

## Heat Balance Method

The heat balance processes introduced briefly in Chapter 2 are described in more detail in this chapter. The resolution of the simultaneous heat balance processes requires an iterative solution. It is not realistic to consider doing that without the aid of a computer. The heat balance concept is fundamental to both the heat balance method (HBM) and the radiant time series method (RTSM). To make the model useful, the concepts must be translated into mathematical form, then arranged into an overall solution scheme. This is done in this chapter.

In the following sections, the fundamentals of the HBM are discussed in the context of the outside face, inside face, and air-heat balances and wall conduction. The discussion is intended to present the physical processes in mathematical terms. This is followed by a brief discussion of the overall solution procedure.

In most cases, the surface heat balances are formulated on the basis of heat flux. The heat flux, which is defined as the rate of heat transfer per unit area $(q / A)$ perpendicular to the direction of transfer, is denoted by the symbol $q^{\prime \prime}$. The subscript on $q^{\prime \prime}$ shows the mode of heat transfer (conduction, convection, or radiation).

### 11.1 Outside Face Heat Balance

The heat balance at the outside face of an exterior zone wall is modeled with four heat exchange processes. Figure 11.1 shows this balance schematically.

The heat balance on the outside face is

$$
\begin{equation*}
q_{\alpha s o l}^{\prime \prime}+q_{\mathrm{LWR}}^{\prime \prime}+q_{c o n v}^{\prime \prime}-q_{k o}^{\prime \prime}=0 \tag{11.1}
\end{equation*}
$$

where
$q_{\alpha s o l}^{\prime \prime}=$ absorbed direct and diffuse solar (short-wavelength) radiation heat flux
$q_{\mathrm{LWR}}^{\prime \prime} \quad=$ net long-wavelength (thermal) radiation flux exchange with the air and surroundings

Figure 11.1 Schematic of surface heat balance.
(Source: Cooling and Heating Load Calculation Principles, Figure 2.1).

## Load Calculation Applications Manual (I-P), Second Edition

$q_{c o n v}^{\prime \prime} \quad=$ convection flux exchange with outdoor air
$q_{k o}^{\prime \prime} \quad=$ conduction heat flux $(q / A)$ into the wall
All terms are positive for net flux to the face except the conduction term, which traditionally is taken to be positive in the direction from outside to inside of the wall. Simplified procedures generally combine the first three terms by using the concept of a sol-air temperature.

The implementation of the HBM described here uses fundamental but simple solar, environmental, and outside convection models to calculate the terms of the outside heat balance where

- $q_{\alpha s o l}^{\prime \prime}$ is calculated using the procedures from Appendix D
- $q_{c o n v}^{\prime \prime}=h_{c o}\left(T_{\text {air }}-T_{\mathrm{o}}\right)$, where $h_{c o}$ is the Yazdanian and Klems (1994) natural convection correlation (McClellan and Pedersen 1997), which is based on air and surface temperatures and is slightly more conservative than the ASHRAE constant coefficient ${ }^{1}$ of $3.1 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F}$.
- $q_{\mathrm{LWR}}^{\prime \prime}$ is a standard radiation exchange formulation between the surface, the sky, and the ground. The radiation heat flux is calculated from the surface absorptance, surface temperature, sky and ground temperatures, and sky and ground view factors.
- The conduction term $q_{k o}^{\prime \prime}$ is calculated using a transfer function method described in Section 11.2.

### 11.2 Wall Conduction Process

There are numerous ways to formulate the wall conduction process (cf. Spitler 1996), which is a topic that has received much attention over the years. Possible ways to model this process include the following:

- Numerical methods (e.g., finite difference, finite volume, and finite element methods)
- Transform methods
- Time series methods

The wall conduction process introduces part of the time dependence inherent in the load calculation process (Figure 11.2).

Figure 11.2 shows face temperatures on the inside and outside faces of the wall element and corresponding inside and outside heat fluxes. All four of these quantities are functions of time. The direct formulation of the process has the two temperature functions as input or known quantities and the two heat fluxes as outputs or resultant quantities.

In all simplified methods, including the RTSM formulation, the face heat transfer coefficients are included as part of the wall element. Then the temperatures in question are the indoor and outdoor air temperatures. This simplification hides the heat transfer coefficients and precludes changing them as airflow conditions change. It also precludes modeling the nonlinear aspects of internal longwave radiation exchange.

Because the heat balances on both sides of the element incorporate both the temperatures and heat fluxes, the solution technique must be able to deal with all quantities simultaneously. From a computational standpoint, the conduction transfer

[^12]

Figure 11.2 Conduction terms of the surface heat balance.
(Source: Cooling and Heating Load Calculation Principles, Figure 2.2).
function (CTF) procedure offers much greater computational speed than numerical methods with little loss of generality. It has therefore been used with the HBM. The CTF formulation relates the conductive heat fluxes to the current and past surface temperatures and the past heat fluxes. The general form for the inside heat flux is

$$
\begin{equation*}
q_{k i}^{\prime \prime}(t)=-z_{o} T_{i, t}-\sum_{j=1}^{n z} z_{j} T_{i, t-j \delta}+Y_{o} T_{o, t}+\sum_{j=1}^{n z} Y_{j} T_{o, t-j \delta}+\sum_{j=1}^{n q} \Phi_{j} q_{k i, i, t-j i}^{\prime \prime} \tag{11.2}
\end{equation*}
$$

and the outside heat flux is

$$
\begin{equation*}
q_{k o}^{\prime \prime}(t)=-Y_{o} T_{i, t}-\sum_{j=1}^{n z} z_{j} T_{i, t-j \delta}+X_{o} T_{o, t}+\sum_{j=1}^{n z} X_{j} T_{o, t-j \delta}+\sum_{j=1}^{n q} \Phi_{j} q_{k o, i, t-j \delta}^{\prime \prime}(1 \tag{11.3}
\end{equation*}
$$

where
$X_{j}=$ outside CTF $, j=0,1, \ldots, n z$
$Y_{j}=\operatorname{cross} \mathrm{CTF}, j=0,1, \ldots, n z$
$Z_{j}=$ inside CTF, $j=0,1, \ldots, n z$
$\Phi_{j}=$ flux CTF $, j=0,1, \ldots, n q$
$T_{i}=$ inside surface temperature
$T_{o}=$ outside face temperature
$q_{k o}^{\prime \prime}=$ conduction heat flux on outside face
$q_{k i}^{\prime \prime}=$ conduction heat flux on inside face
The subscript following the comma indicates the time period for the quantity in terms of the time step $\sigma$ (e.g., $X_{l}$ is applied to the temperature one time step earlier). The first terms in the series (those with subscript $O$ ) have been separated from the rest to facilitate solving for the current temperature in the solution scheme.

The two summation limits, $n z$ and $n q$, are dependent on the wall construction and somewhat dependent on the scheme used for calculating the CTFs. If $n q=0$, the CTFs generally are referred to as response factors, but then theoretically $n z$ is infinite. The values for $n z$ and $n q$ generally are set to minimize the amount of computation. Procedures for determining CTFs are cited by Spitler (1996), and one procedure for computing CTFs is described in detail by Hittle (1979).

## Load Calculation Applications Manual (I-P), Second Edition

### 11.3 Inside Face Heat Balance

The heart of the HBM is the internal heat balance involving the inside faces of the zone surfaces. This heat balance generally is modeled with four coupled heat transfer components, as shown in Figure 11.3:

1. Conduction through the building element
2. Convection to the room air
3. Shortwave radiant absorption and reflection
4. Longwave radiant interchange

The incident shortwave radiation comes from the solar radiation that enters the zone through windows and that is emitted from internal sources such as lights. The longwave radiant interchange includes the absorption and emittance from low-temperature radiation sources, such as zone surfaces, equipment, and people. The inside face heat balance for each face can be written as follows:

$$
\begin{equation*}
q_{\mathrm{LWX}}^{\prime \prime}+q_{\mathrm{SW}}^{\prime \prime}+q_{\mathrm{LWS}}^{\prime \prime}+q_{k i}^{\prime \prime}+q_{s o l}^{\prime \prime}+q_{c o n v}^{\prime \prime}=0 \tag{11.4}
\end{equation*}
$$

where
$q_{\text {LWX }}^{\prime \prime \prime}=$ net long-wavelength radiant exchange flux between zone surfaces
$q_{\mathrm{SW}}^{\prime \prime}=$ net shortwave radiation flux to surface from lights
$q_{\text {LWS }}^{\prime \prime}=$ longwave radiation flux from equipment in zone
$q_{s o l}^{\prime \prime} \quad=$ transmitted solar radiation flux absorbed at surface
$q_{k i}^{\prime \prime} \quad=$ conduction flux through wall
$q_{c o n v}^{\prime \prime}=$ convection heat flux at zone air
The models for these heat exchange components will be described in the following sections.

### 11.3.1 Conduction, $\mathrm{q}_{\mathrm{ki}}$

This contribution to the inside face heat balance is the wall conduction term expressed by Equation 11.2. This represents the heat transfer behind the inside face of the building element.

Figure 11.3 Inside face heat balance.
(Source: Cooling and Heating Load Calculation Principles, Figure 2.3).

### 11.3.2 Internal Radiation Modeling

## Longwave (LW) Radiation Exchange Among Zone Surfaces, $q_{L W X}$

There are two limiting cases for internal longwave (LW) radiation exchange that are easily modeled:

1. The zone air is completely transparent to LW radiation.
2. The zone air completely absorbs LW radiation from the surfaces within the zone.

The limiting case of completely absorbing air has been used for load calculations and also in some energy analysis calculations. This model is attractive because it can be formulated simply using a combined radiation and convection heat transfer coefficient from each surface to the zone air. However, it oversimplifies the zone surface exchange problem. Accordingly, most heat balance formulations treat air as completely transparent.

Thus, the LW radiation exchange among the surfaces in the zone can be formulated directly. The HBM procedure in this manual uses a mean radiant temperature exchange formulation, which uses approximate view factors but retains very good accuracy (Liesen and Pedersen 1997).

## Internal Furnishings

Furniture in a zone has the effect of increasing the amount of surface area and can participate in the radiant and convective heat exchanges. Furniture also adds thermal mass to the zone. These two changes affect the time response of the zone cooling load in opposite ways. The added area tends to shorten the response time, while the added mass tends to lengthen the response time. The proper modeling of furniture is an area that needs further research, but the heat balance formulation allows the effect to be modeled in a realistic manner by including the furniture surface area and thermal mass in the heat exchange process.

## LW Radiation from Internal Sources

The traditional model for this source is to define a radiative/convective split for the heat introduced into a zone from equipment. The radiative part is then distributed over the surfaces within the zone in some prescribed manner. This, of course, is not a completely realistic model, and it departs from the heat balance principles. However, it is virtually impossible to treat this source in any more detail since the alternative would require knowledge of the placement and surface temperatures of all equipment.

## Shortwave Radiation from Lights

The short-wavelength radiation from lights is distributed over the surfaces in the zone in some prescribed manner. In many cases, this is not a very large cooling load component.

### 11.3.3 Transmitted Solar Radiation

Currently available window data uses the solar heat gain coefficient (SHGC) as described by Wright (1995). This has the effect of lumping the transmitted and absorbed solar heat gains together. However, using the number of panes, window description, SHGC, and visual transmittance as a guide, a roughly equivalent window can be selected from Table 3.7, which gives fundamental properties such as angledependent transmittance, reflectance, and layer absorptances. With these properties available, a heat balance model can be made on the individual panes or the inside and outside faces of the window. The latter approach is described by Nigusse (2007). Transmitted solar radiation also is distributed over the surfaces in the zone in a pre-

## Load Calculation Applications Manual (I-P), Second Edition

scribed manner. It would be possible to calculate the actual position of beam solar radiation, but that would involve partial surface irradiation, which is inconsistent with the rest of the zone model that assumes uniform conditions over an entire surface.

The current procedures incorporate a set of prescribed distributions. Since the heat balance approach can deal with any distribution function, it is possible to change the distribution function if it seems appropriate.

### 11.3.4 Convection to Zone Air

The convection flux is calculated using the heat transfer coefficients as follows:

$$
\begin{equation*}
q_{c o n v}^{\prime \prime}=h_{c}\left(T_{a}-T_{s}\right) \tag{11.5}
\end{equation*}
$$

The inside convection coefficients $h_{c}$ presented in the ASHRAE Handbook-Fundamentals [2013] and used in most load calculation procedures and energy programs are based on very old natural convection experiments and do not accurately describe the heat transfer coefficients that are present in a mechanically ventilated zone. In previous calculation procedures, these coefficients were combined with radiative heat transfer coefficients and could not be readily changed. The heat balance formulation keeps them as working parameters. In this way, new research results can be incorporated into the procedures. It also will permit determining the sensitivity of the load calculation to these parameters.

### 11.4 Air Heat Balance

In heat balance formulations aimed at determining cooling loads, the capacitance of the air in the zone is neglected and the air heat balance is done as a quasi-steady balance in each time period. There are four contributors to the air heat balance: convection from the zone surfaces, infiltration and ventilation introduced directly into the zone, and the HVAC system air. The air heat balance may be written as

$$
\begin{equation*}
q_{c o n v}+q_{C E}+q_{\mathrm{IV}}+q_{s y s}=0 \tag{11.6}
\end{equation*}
$$

where
$q_{\text {conv }}=$ convection heat transfer from the surfaces
$q_{C E}=$ convective part of internal loads
$q_{\mathrm{IV}}=$ sensible load due to infiltration and direct zone ventilation air
$q_{s y s}=$ heat transfer to/from the HVAC system

### 11.4.1 Convection from Surfaces

The contribution of convection from surfaces is expressed using the convective heat transfer coefficient, as follows:

$$
\begin{equation*}
q_{\text {conv }}=\sum_{i=1}^{\text {nsurfaces }} h_{c, i} A_{i}\left(T_{a}-T_{s, i}\right) \tag{11.7}
\end{equation*}
$$

### 11.4.2 Convective Parts of Internal Loads, $\mathrm{q}_{\mathrm{CE}}$

This component is the companion part of the radiant contribution from internal loads described previously. It is added directly into the air heat balance. Such a treatment also violates the tenets of the heat balance, since the surfaces producing the
azarnasim
internal loads exchange heat with the zone air through normal convective processes. However, the details required to include this component in the heat balance generally are not available, and its direct inclusion into the air heat balance is a reasonable approach.

### 11.4.3 Infiltration, $q_{\text {IV }}$

Any air that enters by way of infiltration is assumed to be immediately mixed with the zone air. The determination of the amount of infiltration air is quite complicated and subject to significant uncertainty. Chapter 5 of this manual presents some procedures for estimating infiltration. In the HBM and RTSM procedures, the infiltration quantity is converted to a number of air changes per hour ( ACH ) and included in the zone air heat balance using the outside temperature at the current hour.

### 11.5 A Framework for the Heat Balance Procedures

To apply the heat balance procedures to calculating cooling loads, it is necessary to develop a suitable framework for the heat transfer processes involved. This takes the form of a general thermal zone for which a heat balance can be applied to its surfaces and air mass. A thermal zone is defined as an air volume at a uniform temperature plus all the heat transfer and heat storage surfaces bounding or inside of that air volume. It is primarily a thermal, not a geometric, concept and can consist of a single room, a number of rooms, or even an entire building. Generally, it parallels the HVAC system concept of the region that is controlled by a single thermostat. Note particularly, however, that such things as furniture are considered part of the thermal zone.

The heat balance procedure for load calculations needs to be flexible enough to accommodate a variety of geometric arrangements, but the procedure also requires that a complete thermal zone be described. Because of the interactions between elements, it is not possible to build up the zone behavior from a component-by-component analysis. To provide the necessary flexibility, a generalized 12-surface zone can be used as a basis. This zone consists of four walls, a roof or ceiling, a floor, and a thermal mass surface. Each of the walls and the roof can include a window (or skylight in the case of the roof). This makes a total of 12 surfaces, any of which may have zero area if it is not present in the zone to be modeled. Such a zone is shown schematically in Figure 11.4.

The 12-surface thermal zone model used in cooling load calculations requires that complex geometries be reduced to the following essential thermal characteristic:

- The equivalent area and approximate orientation of each surface
- The construction of each surface
- The environmental conditions on both sides of each surface

The 12-surface model captures these essentials without needlessly complicating the procedure. These surfaces provide the connections between the outside, inside, and zone air heat balances and constitute the minimum general set of surfaces that will accommodate a full heat balance calculation.

When using heat-balance-based procedures to calculate cooling loads for various building configurations and conditions, it is helpful to think in terms of the basic zone model and the three zone heat balances.

## Load Calculation Applications Manual (I-P), Second Edition

### 11.6 Implementing the Heat Balance Procedure

### 11.6.1 The Heat Balance Equations

The heat balance processes for the general thermal zone are formulated for a 24 -hour steady periodic condition. The primary variables in the heat balance for the general zone are the 12 inside face temperatures and the 12 outside face temperatures at each of the 24 hours as described in the previous section. The first subscript $i$ is assigned as the surface index, and the second subscript $j$ as the hour index, or, in the case of CTFs, the sequence index. Then, the primary variables are
$T_{s o, i, j}=$ outside face temperature, $i=1,2, \ldots 12 ; j=1,2, \ldots 24$
$T_{s i, i, j}=$ inside face temperature, $i=1,2, \ldots 12 ; j=1,2, \ldots 24$
In addition, the variable $q_{\mathrm{sys} j}=$ cooling load, $j=1,2 \ldots 24$.
Equations 11.1 and 11.3 are combined and solved for $T_{s o}$ to produce 12 equations applicable in each time step:

$$
\begin{align*}
T_{s o_{i, j}}= & \frac{\sum_{k=1}^{n z} T_{s i_{i, j-k}} Y_{i, k}-\sum_{k=1}^{n z} T_{s o_{i, j-k}} X_{i, k}-\sum_{k=1}^{n q} \Phi_{i, k} q_{k o_{i, j-k}}}{X_{i, 0}+h_{c o_{i, j}}}  \tag{11.8}\\
& +\frac{q_{o s o o_{i, j}}^{\prime \prime}+q_{\mathrm{LWR}_{i, j}^{\prime \prime}}+T_{s i_{i, j}} Y_{i, 0}+T_{o_{j}} h_{c o_{i, j-k}}}{X_{i, 0}+h_{c o_{i, j}}}
\end{align*}
$$

where
$Y_{i, k} \quad=\operatorname{cross} \mathrm{CTF}, k=0,1, \ldots n z, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$X_{i, k} \quad=$ inside CTF, $k=0,1, \ldots n z, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$\Phi_{i, k}=$ flux CTF $, k=1,2, \ldots n q, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$T_{s i} \quad=$ inside face temperature, ${ }^{\circ} \mathrm{F}$
$T_{\text {so }} \quad=$ outside face temperature, ${ }^{\circ} \mathrm{F}$
$q_{k o}^{\prime \prime} \quad=$ conductive heat flux $(q / A)$ into the wall, Btu $/ \mathrm{h} \cdot \mathrm{ft}^{2}$

Figure 11.4 Schematic view of general heat balance zone.
(Source: Cooling and Heating Load Calculation Principles, Figure 10.1).

$$
\begin{aligned}
q_{o s o l}^{\prime \prime}= & \text { absorbed direct and diffuse solar (short-wavelength) radiant heat } \\
& \text { flux, } \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}
\end{aligned} \quad \begin{aligned}
& \\
& q_{\mathrm{LWR}}^{\prime \prime}= \text { net long-wavelength (thermal) radiant flux exchange with the air and sur- } \\
& \text { roundings, } \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}
\end{aligned}
$$

Also, $h_{c o}$ is the outside convection coefficient, introduced by using Equation 11.5. This equation shows the need for separating the first term of the CTF series, $X_{i, 0}$, because in that way the contribution of the current surface temperature to the conduction flux can be collected with the other terms involving that temperature. McClellan and Pedersen (1997) present alternative equations for the outside temperature, depending on the outside heat transfer model that is chosen.

Equations 11.2 and 11.4 are combined and solved for $T_{s i}$ to produce the next 12 equations for the inside surface temperatures:

$$
\begin{equation*}
T_{s i_{i, j}}=\frac{T_{s o_{i, j}} Y_{i, 0}+\sum_{k=1}^{n z} T_{s o_{i, j-k}} Y_{i, k}-\sum_{k=1}^{n z} T_{s i_{i, j-k}} Z_{i, k}+\sum_{k=1}^{n q} \Phi_{i, k} q_{k i_{i, j-k}}^{\prime \prime \prime}}{Z_{i, 0}+h_{c i_{i, j}}} \tag{11.9}
\end{equation*}
$$

where
$Y_{i, k}=\operatorname{cross} \mathrm{CTF}$ for surface $\mathrm{i}, k=0,1, \ldots n z, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$Z_{i, k}=$ inside CTF for surface $\mathrm{i}, k=0,1, \ldots n z, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$\Phi_{i, k}=$ flux CTF for surface $\mathrm{i}, k=1,2, \ldots n q, \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$T_{s i}=$ inside face temperature, ${ }^{\circ} \mathrm{F}$
$T_{s o}=$ outside face temperature, ${ }^{\circ} \mathrm{F}$
$T_{a}=$ zone air temperature, ${ }^{\circ} \mathrm{F}$
$h_{c i}=$ convective heat transfer coefficient on the inside, obtained from Equation 11.5, Btu/h $\cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$

Other heat flux terms are defined in Section 11.3. Note that in Equations 11.8 and 11.9 the opposite surface temperature at the current time appears on the right-hand side. The two equations could be solved simultaneously to eliminate those variables. Depending on the order of updating the other terms in the equations, this can have a beneficial effect on the solution stability.

The remaining equation comes from the air-heat balance, Equation 11.6. This provides the cooling load $q_{s y s}$ at each time step:

$$
\begin{equation*}
q_{s y s}=q_{C E}+q_{\mathrm{IV}}+q_{c o n v} \tag{11.10}
\end{equation*}
$$

where
$q_{\mathrm{CE}}=$ convective part of internal loads, Btu/h
$q_{\mathrm{IV}}=$ sensible load due to infiltration and ventilation air, Btu/h
$q_{s y s}=$ heat transfer to/from the HVAC system, Btu/h
$q_{c o n v}=$ convected heat transfer from zone surfaces, Btu/h

### 11.6.2 Overall HBM Iterative Solution Procedure

The iterative heat balance procedure is quite simple. It consists of a series of initial calculations that proceed sequentially, followed by a double iteration loop. This is shown in the following procedure:

## Load Calculation Applications Manual (I-P), Second Edition

1. Initialize areas, properties, and face temperatures for all surfaces, for all 24 hours.
2. Calculate incident and transmitted solar fluxes for all surfaces and hours.
3. Distribute transmitted solar energy to all inside faces, for all 24 hours.
4. Calculate internal load quantities, for all 24 hours.
5. Distribute longwave (LW), shortwave (SW), and convective energy from internal loads to all surfaces for all 24 hours.
6. Calculate infiltration and ventilation loads for all 24 hours.
7. Iterate the heat balance according to the following pseudo-code scheme:

For Day = 1 to MaxDays (repeat day for convergence)
For $j=1$ to 24 (hours of the day)
For SurfaceIter $=1$ to MaxSurfIter
For $i=1$ to 12 (surfaces)
Evaluate Equations 11.8 and 11.9
Next $i$
Next SurfaceIter
Next $j$
If not converged, NextDay
8. Display results.

It has been found that about four surface iterations (MaxSurfIter) are sufficient to provide convergence. The convergence check on the day iteration is based on the difference between the inside and the outside conductive heat flux terms $q_{k}$.

## Appendix A <br> Psychrometric Processes-Basic Principles

Psychrometrics and psychrometric processes are used in the conversion of cooling and heating loads into equipment loads for system design and optimization. Psychrometrics enable the designer to determine air quantities and air conditions, which can be used for equipment selection and duct and piping design. This section deals with the fundamental properties of moist air and the basic processes used in HVAC systems. More detailed information is available in the ASHRAE Handbook, particularly the Fundamentals and the HVAC Systems and Equipment volumes.

There are two methods used to determine the properties of moist air. The calculations can be made using the perfect gas relations. Or, the various properties can be determined using a psychrometric chart, which is based on a somewhat more rigorous analysis. For all practical purposes, properties computed from the perfect gas relations agree very well with those read from a psychrometric chart. Many computer programs are available to compute the properties of moist air, and these programs may display a chart as well.

The psychrometric chart is a valuable visual aid in displaying the processes in the HVAC system. Figure A. 1 is the abridged ASHRAE Psychrometric Chart 1 (ASHRAE 1992) for the normal temperatures of air-conditioning applications and for a standard barometric pressure of 29.921 in . of mercury. Charts for other temperature ranges and other altitudes are also available. For example, ASHRAE Psychrometric Chart 4 (ASHRAE 1992) is for an elevation of 5000 ft . The various properties may be identified on the chart where dry-bulb temperature is plotted on the horizontal axis and humidity ratio is plotted on the vertical axis. Chapter 1 of the ASHRAE Hand-book-Fundamentals (2013) defines the various parameters and gives the various relations from which the properties may be computed. Local atmospheric pressure is an important fundamental property and depends on local elevation. This property will be discussed extensively in later sections. Other properties shown on the psychrometric chart are as follow:

- Enthalpy—given on the left-hand inclined scale with lines sloping downward to the right with units of $\mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}$.
- Relative humidity-shown by lines curving upward from the lower left to upper right and given in percent. The $100 \%$ line representing saturated air is the uppermost line.
- Wet-bulb temperatures-shown along the $100 \%$ relative humidity line in ${ }^{\circ} \mathrm{F}$. Note that the wet-bulb temperature lines are nearly parallel with the enthalpy lines, indicating that enthalpy is mainly a function of wet-bulb temperature. Also, note that dry-bulb temperature equals wet-bulb temperature when the air is saturated, $100 \%$ relative humidity.
- Specific volume-shown by straight lines inclined downward from upper left to lower right. The lines are widely spaced; however, the change in volume is small across the chart and visual interpolation is adequate. Units are $\mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$.
- Dew-point temperature-not shown directly on the chart but can be easily determined at any state point by moving horizontally to the left to the $100 \%$ relative humidity line. The wet-bulb temperature at that point is the dew-point temperature in ${ }^{\circ} \mathrm{F}$.

## Load Calculation Applications Manual (I-P), Second Edition

Figure A. 1 ASHRAE Psychrometric Chart 1 (ASHRAE 1992).

## A. 1 Basic Data and Standard Conditions

The approximate composition of dry air by volume is as follows:

| Nitrogen | 0.78084 |
| :--- | :--- |
| Oxygen | 0.20948 |
| Argon | 0.00934 |
| Carbon dioxide | 0.00031 |
| Neon, helium, methane, sulfur dioxide |  |
| Hydrogen and other gases | 0.00003 |

When the last group, considered to be inert, is included with the nitrogen, the resulting molecular weight is 28.965 and the gas constant is $53.352 \mathrm{ft} \cdot \mathrm{lb}_{\mathrm{f}} /\left(\mathrm{lb}_{\mathrm{a}} \cdot \mathrm{R}\right)$. This value of the gas constant is used with the perfect gas relations. The U.S. Standard Atmosphere is defined as follows (ASHRAE 2013):

- Acceleration due to gravity is constant at $32.174 \mathrm{ft} / \mathrm{s}^{2}$.
- Temperature at sea level is $59.0^{\circ} \mathrm{F}$.
- Pressure at sea level is 29.921 in . of mercury.
- The atmosphere consists of dry air, which behaves as a perfect gas.

Moist air is a two-component mixture of dry air and water vapor. The amount of water vapor may vary from zero to a maximum amount dependent on pressure and
temperature. The latter condition is referred to as saturated air. The molecular weight of water is 18.015 and the gas constant is $85.78 \mathrm{ft} \cdot \mathrm{lb}_{\mathrm{f}} /\left(\mathrm{lb}_{\mathrm{v}} \cdot \mathrm{R}\right)$, which is used with the perfect gas relations.

Local atmospheric pressure and temperature vary with altitude or elevation. Table A.1, taken from the ASHRAE Handbook-Fundamentals (2013), gives pressure and temperature as a function of altitude. The pressures are typical of local barometric pressure on the earth's surface at the elevations shown. However, the local temperatures on the earth's surface are influenced to a greater extent by climatic conditions, and other data should be used. For system design and load calculations, it is suggested that local weather data or the design temperatures from Chapter 4 of this manual be used. This same data gives the elevation for the various cities from which the local atmospheric pressure can be estimated. For elevations less than or equal to 30,000 feet,

$$
\begin{equation*}
p=14.696\left(1-6.8754 \cdot 10^{-6} Z\right)^{5.2559} \tag{A.1}
\end{equation*}
$$

where
$p=$ local atmospheric pressure, psia
$Z=$ local elevation, ft above sea level
The use of the proper local atmospheric pressure in calculations is very important to ensure accurate results.

## A. 2 Basic Moist Air Processes

The most powerful analytical tools of the air-conditioning design engineer are the conservation of energy (first law of thermodynamics) or energy balance, and the conservation of mass or mass balance. These conservation laws are the basis for the analysis of moist air processes. It is customary to analyze these processes by using the bulk average properties at the inlet and outlet of the device being studied. In actual practice, the properties may not be uniform across the flow area, especially at the outlet, and a considerable length may be necessary for complete mixing.

In this section we consider the basic processes that are a part of the analysis of most systems. The psychrometric chart will be used extensively to illustrate the processes.

## Heat Transfer Processes in General

In almost all cases of design or analysis of heat transfer processes, the fluids such as moist air are flowing at a steady rate, often called steady flow. Therefore, the energy balance for a moist air-cooling process can be written

$$
\begin{equation*}
m_{a} h_{1}=m_{a} h_{2}+q+m_{w} h_{w} \tag{A.2}
\end{equation*}
$$

or

$$
\begin{equation*}
q=m_{a}\left(h_{1}-h_{2}\right)-m_{w} h_{w} \tag{A.3}
\end{equation*}
$$

where
$q=$ heat transfer rate, Btu/h
$m_{a}=$ mass flow rate of dry air, $\mathrm{lb}_{\mathrm{a}} / \mathrm{h}$
$m_{w}=$ mass flow rate of water, $\mathrm{lb}_{\mathrm{w}} / \mathrm{h}$
$h=$ enthalpy, Btu/ $\mathrm{lb}_{\mathrm{a}}$ or Btu/ $\mathrm{lb}_{\mathrm{w}}$
The subscripts 1 and 2 refer to the entering and leaving air. Equation A. 2 assumes that the system does not do any work and kinetic and potential energy changes are zero. Work will be considered later. It should be noted that the mass flow rate $m_{a}$ is

## Load Calculation Applications Manual (I-P), Second Edition

for dry air and enthalpy $h_{a}$ is based on a one-pound mass of dry air. The term $m_{w} h_{w}$, the energy of the liquid water, is often very small and can be neglected. It will be assumed zero for the following discussion and reintroduced later. As Equation A. 2 is written, the heat transfer rate $q$ is positive for heat transfer away from the airstream. If heating and humidification were being considered, the terms $q$ and $m_{w} h_{w}$ would be on the opposite side of the equation and it would be written as follows:

$$
\begin{equation*}
q=m_{a}\left(h_{2}-h_{1}\right)-m_{w} h_{w} \tag{A.4}
\end{equation*}
$$

In practice, the direction of the heat transferred is obvious by the nature of the problem. Equations A.2-A. 4 are valid for any steady-flow heat transfer process, with the assumptions noted. The enthalpy difference $h_{2}-h_{1}$ is made up of two parts:

$$
\begin{equation*}
h_{2}-h_{1}=c_{p}\left(t_{2}-t_{1}\right)+\Delta h\left(W_{2}-W_{1}\right) \tag{A.5}
\end{equation*}
$$

where
$c_{p}=$ specific heat of moist air, $\mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{a}} \cdot{ }^{\circ} \mathrm{F}\right)$
$t=$ dry-bulb temperature, ${ }^{\circ} \mathrm{F}$
$W=$ humidity ratio, $\mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}$
$\Delta h=$ change in enthalpy required to vaporize or condense 1 lb of water, $\mathrm{Btu} / \mathrm{lb}_{\mathrm{v}}$
The first term on the right-hand side of Equation A. 5 represents the heat transferred to change the air temperature from $t_{1}$ to $t_{2}$. This is referred to as sensible heat transfer. The other term in Equation A. 5 represents the heat transferred to change the humidity ratio from $W_{1}$ to $W_{2}$. This is referred to as latent heat transfer. Then, $h_{2}-h_{1}$ is proportional to the total heat transfer, and Equation A. 5 may be substituted into Equation A. 4 to obtain

$$
\begin{equation*}
q=m_{a}\left(h_{2}-h_{1}\right)=m_{a}\left[c_{p}\left(t_{2}-t_{1}\right)+\Delta h\left(W_{2}-W_{1}\right)\right] \tag{A.6}
\end{equation*}
$$

where the term $m_{w} h_{w}$ has been neglected.
It is customary to use the volume flow rate of moist air in cfm in design calculations rather than mass flow rate $m_{a}$. These two quantities are related by the specific volume $v$, another property shown on the psychrometric chart, as follows:

$$
\begin{equation*}
m_{a}=60(\mathrm{cfm}) / v_{a}, \tag{A.7}
\end{equation*}
$$

where $m_{a}$ is in $\mathrm{lb}_{\mathrm{a}} / \mathrm{h}$. The specific volume in $\mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$, computed or read from the psychrometric chart, is a very useful parameter. It is important that the volume flow rate, cfm , and specific volume $v$ be specified at the same state or point on the psychrometric chart. The specific volume $v_{a}$ may also be computed as follows using the ideal gas law:

$$
\begin{equation*}
v_{a}=(R T) / P_{a} \tag{A.8}
\end{equation*}
$$

where
$R=$ gas constant for dry air, 53.352, $\mathrm{ft} \cdot \mathrm{lb}_{\mathrm{f}} /\left(\mathrm{lb}_{\mathrm{m}} \cdot{ }^{\circ} \mathrm{R}\right)$
$T=$ absolute air temperature, $(t+460),{ }^{\circ} \mathrm{R}$
$P_{a}=$ partial pressure of dry air, $\mathrm{lb}_{\mathrm{f}} / \mathrm{ft}^{2}$
The partial pressure of the air depends on the local barometric pressure and the humidity ratio of the moist air. For design purposes, partial pressure may be assumed equal to the local barometric pressure, which is proportional to the elevation above sea level (Table A.1). Table A. 2 gives values of $v_{a}$ for different elevations and temperatures, covering the range of usual design conditions. This data is useful in practical calculations.

The specific heat $c_{p}$ in Equation A. 6 is for the moist air but is based on 1 lb mass of dry air. So,

$$
\begin{equation*}
c_{p}=c_{p a}+W c_{p v} \tag{A.9}
\end{equation*}
$$

where
$c_{p a}=$ specific heat of dry air, $0.24 \mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{a}} \cdot{ }^{\circ} \mathrm{F}\right)$
$c_{p v}=$ specific heat of water vapor, $0.44 \mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{v}}{ }^{\cdot} \mathrm{F}\right)$
$W=$ humidity ratio, $\mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}$
The humidity ratio depends on the air temperature and pressure; however, for typical HVAC calculations, a value of $0.01 \mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}$ is often used. Then,

$$
c_{p}=0.24+0.01(0.44)=0.244 \mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{a}} \cdot{ }^{\circ} \mathrm{F}\right)
$$

This value is used extensively in Chapter 9 where practical psychrometrics are discussed.

The enthalpy change $\Delta h_{w}$ in Equations A. 5 and A. 6 is relatively constant in the range of air-conditioning processes, and a value of $1076 \mathrm{Btu} / \mathrm{lb}_{\mathrm{v}}$ is often assumed. This value is representative of the enthalpy change for 1 lb of water changing from saturated vapor in the moist air to a saturated liquid when condensed.

## Sensible Heating or Cooling of Moist Air

When air is heated or cooled without the loss or gain of moisture, the process yields a straight horizontal line on the psychrometric chart because the humidity ratio is constant. This type of process is referred to as sensible heating or cooling. Such processes can occur when moist air flows through a heat exchanger. Process 1-2 in Figure A. 2 represents sensible heating, while the process 2-1 would be sensible cooling. The heat transfer rate for such a process is given by Equations A. 3 or A. 4 for heating.

$$
\begin{equation*}
q=m_{a}\left(h_{2}-h_{1}\right)=m_{a}\left[c_{P}\left(t_{2}-t_{1}\right)+\Delta h\left(W_{2}-W_{1}\right)\right] \tag{A.10}
\end{equation*}
$$

Since there is no transfer of moisture, $W_{2}-W_{1}=0$ and

$$
\begin{equation*}
q_{s}=m_{a}\left(h_{2}-h_{1}\right)=m_{a} c_{P}\left(t_{2}-t_{1}\right) \tag{A.11}
\end{equation*}
$$

Figure A. 2 Sensible heating and cooling process.
(Source: Cooling and Heating Load Calculation Principles, Figure D2).

where $q_{s}$ denotes a sensible heat transfer process. Note that the heat transfer rate $q_{s}$ is still proportional to the enthalpy change $h_{2}-h_{1}$. Substituting Equation A. 7 for $m_{a}$ yields

$$
\begin{equation*}
q_{s}=60(\mathrm{cfm}) c_{P}\left(t_{2}-t_{1}\right) / v_{a} \tag{A.12}
\end{equation*}
$$

When a constant value of $0.244 \mathrm{Btu} /\left(\mathrm{lb}_{\mathrm{a}} \cdot{ }^{\circ} \mathrm{F}\right)$ is substituted for $c_{p}$ in Equation A.12,

$$
\begin{equation*}
q_{s}=14.64(\mathrm{cfm})\left(t_{2}-t_{1}\right) / v_{a} \tag{A.13}
\end{equation*}
$$

Further, when the standard value of $13.28 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$ is substituted for $v_{a}$ in Equation A.6b,

$$
\begin{equation*}
q_{s}=1.10(\mathrm{cfm})\left(t_{2}-t_{1}\right) \tag{A.14}
\end{equation*}
$$

This is a commonly used relationship, but its limitations must be kept in mind. The constant may be easily adjusted using Table A. 2 and Equation A.13. A slightly smaller constant of 1.08 is often used for heating conditions rather than 1.10 ; however, the difference is not significant. It is far more important to recognize that local atmospheric pressure or elevation has a greater effect. For example, the specific volume $v$ of air at 5000 ft elevation and $59^{\circ} \mathrm{F}$ is about $16.0 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$, and the constant in Equation A. 14 would be 0.90 -a significant difference of about $20 \%$.

## Example A. 1 Sensible Heating

Find the heat transfer required to heat 1500 cfm of atmospheric air at $60^{\circ} \mathrm{F}$ and $90 \%$ relative humidity to $120^{\circ} \mathrm{F}$, without transfer of moisture to or from the air. Assume standard sea-level pressure.

Solution: Since this is a sensible heat transfer process, Equation A. 12 or A. 13 may be used to compute the heat transfer rate. Using A.6a,

$$
q_{s}=60(\mathrm{cfm}) c_{p}\left(t_{2}-t_{1}\right) / v_{a}=60 \cdot 1500 \cdot 0.244(120-60) / 13.278=99,232 \mathrm{Btu} / \mathrm{h},
$$

where $v$ is from Table A. 2 at zero elevation and $60^{\circ} \mathrm{F} / 55^{\circ} \mathrm{F}$. Suppose this process took place at a location where the elevation above sea level was 5000 ft . Using Table A.2, the specific volume $v$ would be $15.991 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$. Then for 1500 cfm at this high altitude using Equation A.6b:

$$
q_{s}=14.64(1500)(120-60) / 15.991=82,396 \mathrm{Btu} / \mathrm{h}
$$

The specific volumes above could have been read from an appropriate psychrometric chart.

## Cooling and Dehumidifying of Moist Air

When moist air is cooled to a temperature below its dew point, some of the water vapor will condense and leave the airstream. This process usually occurs with cooling coils and is one of the most important in HVAC design. Figure A. 3 shows the process on the psychrometric chart. Although the actual process path will vary depending on the type of surface, surface temperature, and flow conditions, the heat and moisture transfer can be expressed in terms of the initial and final states. In the previous section, where heat transfer was discussed in general, the fact that some liquid water leaves the system as condensate was neglected. The condensate has some energy, although it is a small amount. The energy balance from Equation A. 3 becomes

Figure A. 3 Cooling and dehumidifying process.
(Source: Cooling and Heating Load Calculation Principles, Figure D3).

$$
\begin{equation*}
q=m_{a}\left(h_{2}-h_{1}\right)-m_{w} h_{w} \tag{A.15}
\end{equation*}
$$

or

$$
\begin{equation*}
q=m_{a}\left[c_{p}\left(t_{2}-t_{1}\right)+\Delta h\left(W_{2}-W_{1}\right)\right]-m_{w} h_{w} \tag{A.16}
\end{equation*}
$$

For cooling, the last term on the right-hand side of Equations A. 15 and A. 16 is quite small compared to the other terms and can usually be neglected, as previously discussed. Then Equation A. 16 is the same as Equation A.6. However, it is much more convenient in this case to use Equation A.15, neglect the last term, and read the enthalpies from a psychrometric chart.

It was noted earlier that the change in enthalpy $\left(h_{1}-h_{2}\right)$ is made up of two parts, sensible and latent. This can be shown conveniently in Figure A.3. Imagine that the process follows the path 1-a-2 instead of path 1-2 as shown. The result is the same because

$$
\begin{equation*}
h_{2}-h_{1}=\left(h_{a}-h_{1}\right)+\left(h_{2}-h_{a}\right) \tag{A.17}
\end{equation*}
$$

Path 1-a represents a latent heat transfer process and path a-2 represents a sensible heat transfer process. Both taken together represent the total heat transfer process. Therefore, this is a convenient way of determining the two quantities rather than using Equation A. 16 to determine the separate quantities. When Equation A. 15 is converted to the volume flow form, using Equation A.7, it becomes

$$
\begin{equation*}
q=60(\mathrm{cfm})\left(h_{1}-h_{2}\right) / v \tag{A.18}
\end{equation*}
$$

where the term $m_{w} h_{w}$ has again been neglected and $v$ may be obtained from a psychrometric chart, computed, or read from Table A.2. When a standard value of $13.28 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$ is used for $v$ in Equation A. 18 it becomes

$$
\begin{equation*}
q=4.5(\mathrm{cfm})\left(h_{1}-h_{2}\right) \tag{A.19}
\end{equation*}
$$

The sensible heat factor (SHF), sometimes called the sensible heat ratio (SHR), is defined as

$$
\begin{equation*}
\mathrm{SHF}=q_{s} / q=\frac{\left(h_{a}-h_{2}\right)}{\left(h_{1}-h_{2}\right)} \tag{A.20}
\end{equation*}
$$

where the enthalpy values are from Figure A.3. The SHF is also shown on the semicircular scale of Figure A.3. Use of this feature will be explained in an example.

## Example A. 2 Cooling

Moist air at $80^{\circ} \mathrm{F} \mathrm{dB}$ and $67^{\circ} \mathrm{F} \mathrm{wB}$ is cooled to $58^{\circ} \mathrm{F} \mathrm{dB}$ and $80 \%$ relative humidity. The volume flow rate of the entering air is 2000 cfm and the condensate leaves at $60^{\circ} \mathrm{F}$. Find the heat transfer rate. Assume standard sea-level pressure.

Solution: Equation A. 15 applies to this process, which is similar to Figure A.3. The term for the condensate will be retained to demonstrate how small it is. The following properties are read from ASHRAE Psychrometric Chart 1 (ASHRAE 1992): $v_{1}=13.85 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}, h_{1}=31.6 \mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}, W_{1}=0.0112 \mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}, h_{2}=22.9 \mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}$, and $W_{2}=$ $0.0082 \mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}$. The enthalpy of the condensate is obtained from the thermodynamic properties of water, $h_{w}=28.08 \mathrm{Btu} / \mathrm{lb}_{\mathrm{w}}$. The enthalpy of liquid water, the condensate, may also be closely estimated by

$$
h_{w}=t_{w}-32
$$

Using Equation A. 18 and retaining the condensate term,

$$
q=60(\mathrm{cfm})\left(h_{1}-h_{2}\right) / v-m_{w} h_{w}
$$

The flow rate of the condensate $m_{w}$ may be found from a mass balance on the water:

$$
m_{v, \text { in }}=m_{v, \text { out }}+m_{w}
$$

or

$$
m_{a} W_{1}=m_{a} W_{2}+m_{w}
$$

and

$$
\begin{equation*}
m_{w}=m_{a}\left(W_{1}-W_{2}\right)=60(\mathrm{cfm})\left(W_{1}-W_{2}\right) / v \tag{A.21}
\end{equation*}
$$

then

$$
\begin{gathered}
q=60(\mathrm{cfm})\left[\left(h_{1}-h_{2}\right)-\left(W_{1}-W_{2}\right) h_{w}\right] / v_{1} \\
q=60(2000)[(31.6-22.9)-(0.0112-0.0082) 28.08] / 13.85 \\
q=8664(8.7-0.084)
\end{gathered}
$$

The last term, which represents the energy of the condensate, is quite insignificant. For most cooling and dehumidifying processes this will be true. Finally, neglecting the condensate term, $q=75,380 \mathrm{Btu} / \mathrm{h}$. A ton of refrigeration is 12,000 $\mathrm{Btu} / \mathrm{h}$. Therefore, $q=6.28$ tons.

Note that the solution to Example A. 2 is very difficult without a psychrometric chart or some other aid such as a computer program. The sensible heat transfer is easily computed using Equation A.11, but the latent heat transfer calculation requires the use of enthalpy or humidity ratio, Equations A. 24 or A.23. These can be calculated from basic principles, but this is a tedious task. Therefore, one of the following three equations is recommended: A.15, A.16, or A.17. Note that the total

## Load Calculation Applications Manual (I-P), Second Edition

heat transfer rate could be computed by $q=q_{\mathrm{s}} / \mathrm{SHF}$, where $q_{\mathrm{S}}$ is obtained from Equation A.11, and the SHF is obtained from a psychrometric chart. Psychrometric computer programs are very useful for problems of this type, particularly for elevations where charts are not available.

As discussed previously, the cooling and dehumidifying process involves both sensible and latent heat transfer, where sensible heat transfer is associated with the decrease in dry-bulb temperature and the latent heat transfer is associated with the decrease in humidity ratio. These quantities may be expressed as

$$
\begin{equation*}
q_{s}=m_{a} c_{p}\left(t_{2}-t_{1}\right) \tag{A.22}
\end{equation*}
$$

and

$$
\begin{equation*}
q=m_{a}\left(W_{2}-W_{1}\right) \Delta h \tag{A.23}
\end{equation*}
$$

By referring to Figure A.3, we may also express the latent heat transfer as

$$
\begin{equation*}
q_{1}=m_{a}\left(h_{1}-h_{a}\right) \tag{A.24}
\end{equation*}
$$

and the sensible heat transfer is given by

$$
\begin{equation*}
q_{s}=m_{a}\left(h_{a}-h_{2}\right) \tag{A.25}
\end{equation*}
$$

The energy of the condensate has been neglected. Recall that

$$
m_{a}=60(\mathrm{cfm}) / v
$$

and obviously

$$
\begin{equation*}
q=q_{s}+q_{1} \tag{A.26}
\end{equation*}
$$

The sensible heat factor SHF, defined as $q_{s} / q$, is shown on the semicircular scale of Figure A.3. The SHF is given on the circular scale by a line parallel to line 1-2, as shown, and has a value of 0.62 in Example A.2.

## Heating and Humidifying Moist Air

This type of process usually occurs during the heating season when it is necessary to add moisture to conditioned air to maintain a healthful relative humidity.

Moist air may be heated and humidified in one continuous process. However, this is not very practical because the physical process would require spraying water on a heating element, resulting in a buildup of scale and dirt and causing consequent maintenance problems.

Warm air is also easier to humidify and can hold more moisture than cool air. Therefore, the air is usually heated, followed by an adiabatic humidification process. Sensible heating was previously discussed; adiabatic humidification will now be considered.

## Adiabatic Humidification

When moisture is added to moist air without the addition of heat, the energy equation becomes

$$
\begin{equation*}
\left(h_{2}-h_{1}\right) /\left(W_{2}-W_{1}\right)=h_{w}=\Delta h /(\Delta W) \tag{A.27}
\end{equation*}
$$

It is important to note in Equation A. 27 that $h_{1}$ and $h_{2}$ are the enthalpies of the moist air in $\mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}$, while $h_{w}$ is the enthalpy of the water, liquid or vapor, used to humidify the air. The direction of the process on the psychrometric chart can vary
considerably. If the injected water is saturated vapor at the dry-bulb temperature, the process will proceed at a constant dry-bulb temperature. If the water enthalpy is greater than the enthalpy of saturated vapor at the dry-bulb temperature, the air will be heated and humidified. If the water enthalpy is less than the enthalpy of saturated vapor at the dry-bulb temperature, the air will be cooled and humidified. Figure A. 4 shows these processes.

One other situation is important. When liquid water at the wet-bulb temperature is injected, the process follows a line of constant wet-bulb temperature, as shown in Figure A.4. The quantity $\Delta h / \Delta W$ is also given on the semicircular scale of the psychrometric chart and is a great aid in solving humidification problems. This is demonstrated in Example A.3.

Figure A. 4 Humidification processes without heat transfer.
(Source: Cooling and Heating Load Calculation Principles, Figure D4).

Example A. 3 Heating and Humidification

Moist air at $60^{\circ} \mathrm{F} \mathrm{dB}$ and $20 \%$ relative humidity enters a heater and humidifier at the rate of 1600 cfm . It is necessary to heat the air followed by adiabatic humidification so that it leaves at a temperature of $115^{\circ} \mathrm{F}$ and a relative humidity of $30 \%$. Saturated water vapor at $212^{\circ} \mathrm{F}$ is injected. Determine the required heat transfer rate and mass flow rate of the vapor. Assume standard sea-level pressure.

Solution: It is first necessary to locate the states, as shown in Figure A. 5 from the given information and Equation A.27, using the protractor feature of the psychrometric chart. Process 1-a is sensible heating; therefore, a horizontal line to the right of state 1 is constructed. The $\Delta h / \Delta W$ scale on the protractor of the ASHRAE Psychrometric Charts (ASHRAE 1992) is designed so that (1) the path of a humidification process can be determined when $\Delta h / \Delta W$ is known or (2) if the process path is known, $\Delta h / \Delta W$ may be determined. For example, referring to Figure A.5, the complete process may be visualized as going from point 1 to point 2 . When these two states are connected by a straight line and a parallel line transferred to the protractor, as shown, $\Delta h / \Delta W$ may be read and used in calculations as required. Also note that in the case of process a-2, an adiabatic process, $\Delta h / \Delta W$ equals $h_{w}$ from Equation A.27. Therefore, because $h_{w}$ is known ( $1150 \mathrm{Btu} / \mathrm{lb}$ ), a parallel line can be transferred from the protractor to the chart to pass through point 2 and intersect the horizontal line from point 1 , which represents the sensible heating process. Point a is thus determined: $t_{a}=111.5^{\circ} \mathrm{F}$. The heat transfer rate is then given by

$$
\begin{equation*}
q=m_{a}\left(h_{a}-h_{1}\right)=60(\mathrm{cfm}) c_{p}\left(t_{a}-t_{1}\right) / v_{1} \tag{A.28}
\end{equation*}
$$

where

$$
\begin{equation*}
m_{a}=60(\mathrm{cfm}) / v_{1} \tag{A.29}
\end{equation*}
$$

and $h_{1}$ and $h_{a}$ are read from ASHRAE Psychrometric Chart 1 (ASHRAE 1992) as 16.7 and $29.2 \mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}$, respectively.

Then,

$$
q=60(1600) \cdot(29.2-16.7) / 13.15=91,255 \mathrm{Btu} / \mathrm{h}
$$

Figure A. 5 Typical heating and humidifying process.
(Source: Cooling and Heating Load Calculation Principles, Figure D5).
or

$$
q=60(1600) \cdot 0.244 \cdot(111.5-60) / 13.15=91,737 \mathrm{Btu} / \mathrm{h}
$$

The mass flow rate of the vapor is given by a mass balance on the water:

$$
\begin{gathered}
m_{v 1}+m_{w}=m_{v 2} \\
m_{a} W_{1}+m_{w}=m_{a} W_{2}
\end{gathered}
$$

and

$$
\begin{equation*}
m_{w}=m_{a}\left(W_{2}-W_{1}\right) \tag{A.30}
\end{equation*}
$$

where $W_{2}$ and $W_{1}$ are read from ASHRAE Psychrometric Chart 1 (ASHRAE 1992) as 0.0194 and $0.0022 \mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}}$, respectively. Then,

$$
m_{w}=7300(0.0194-0.0022)=125.6 \mathrm{lb}_{w} / \mathrm{h}
$$

which is saturated water vapor at $212^{\circ} \mathrm{F}$.

## Adiabatic Mixing of Two Streams of Moist Air

The mixing of airstreams is quite common in air-conditioning systems. The mixing process usually occurs under adiabatic conditions and with steady flow. An energy balance gives

$$
\begin{equation*}
m_{a 1} h_{1}+m_{a 2} h_{2}=m_{a 3} h_{3} \tag{A.31}
\end{equation*}
$$

where the subscripts 1 and 2 refer the airstreams being mixed and 3 refers to a mixed airstream. The mass balance on the dry air is

$$
\begin{equation*}
m_{a 1}+m_{a 2}=m_{a 3} \tag{A.32}
\end{equation*}
$$

The mass balance on the water vapor is

$$
\begin{equation*}
m_{a 1} W_{1}+m_{a 2} W_{2}=m_{a 3} W_{3} \tag{A.33}
\end{equation*}
$$

Combining Equations A. 31 through A. 33 gives the following result:

$$
\begin{equation*}
\frac{h_{2}-h_{3}}{h_{1}-h_{3}}=\frac{W_{2}-W_{3}}{W_{1}-W_{3}}=\frac{m_{a 2}}{m_{a 3}} \tag{A.34}
\end{equation*}
$$

The state of the mixed streams must lie on a straight line between states 1 and 2 as shown in Figure A.6. It may be further inferred from Equation A. 34 that the lengths of the various line segments are proportional to the mass flow rates of the two streams to be mixed. So,

$$
\begin{equation*}
\frac{m_{a 1}}{m_{a 2}}=\frac{\overline{32}}{\overline{13}} ;=\frac{m_{a 1}}{m_{a 3}}=\frac{\overline{32}}{\overline{12}} ; \frac{m_{a 2}}{m_{a 3}}=\frac{\overline{13}}{\overline{12}} \tag{A.35}
\end{equation*}
$$

This fact provides a very convenient graphical procedure for solving mixing problems in contrast to the use of Equations A. 31 through A. 33 .

It should be noted that the mass flow rate is used in the procedure; however, the volume flow rates may be used to obtain approximate results.

## Example A. 4 Mixing

Two thousand cfm of air at $100^{\circ} \mathrm{F} \mathrm{dB}$ and $75^{\circ} \mathrm{F}$ wB are mixed with 1000 cfm of air at $60^{\circ} \mathrm{F} \mathrm{dB}$ and $50^{\circ} \mathrm{F} \mathrm{wB}$. The process is adiabatic, at a steady flow rate and at standard sea-level pressure. Find the condition of the mixed stream.

Solution: A combination graphical and analytical solution is first obtained. The initial states are first located on ASHRAE Psychrometric Chart 1 (ASHRAE 1992) as illustrated in Figure A. 6 and connected with a straight line.

Figure A. 6 Adiabatic mixing process.
(Source: Cooling and Heating Load Calculation Principles, Figure D6).

Equations A. 32 and A. 33 are combined to obtain

$$
\begin{equation*}
W_{3}=W_{1}+\frac{m_{a 2}}{m_{a 3}}\left(W_{2}-W_{1}\right) \tag{A.36}
\end{equation*}
$$

By using the property values from ASHRAE Psychrometric Chart 1 (ASHRAE 1992) and Equation A.7, we obtain

$$
\begin{gathered}
m_{a 1}=\frac{1000(60)}{13.21}=4542 \mathrm{lb}_{\mathrm{a}} / \mathrm{h} \\
m_{a 2}=\frac{2000(60)}{14.4}=8333 \mathrm{lb}_{\mathrm{a}} / \mathrm{h} \\
W_{3}=0.0053+\frac{8333}{(4542+8333)}(0.013-0.0053)=0.0103 \mathrm{lb}_{\mathrm{v}} / 1 \mathrm{~b}_{\mathrm{a}} \\
W_{3}=0.0052+\frac{1.111}{(0.606+1.111)}(0.013-0.0052)=0.0102 \mathrm{~kg} / \mathrm{kg}_{\mathrm{da}}
\end{gathered}
$$

The intersection of $W_{3}$ with the line connecting states 1 and 2 gives the mixture state 3 . The resulting dry-bulb temperature is $86^{\circ} \mathrm{F}$ and the wet-bulb temperature is $68^{\circ} \mathrm{F}$.

The complete graphical procedure could also be used where the actual lengths of the process lines are used:

$$
\frac{\overline{13}}{\overline{12}}=\frac{m_{a 2}}{m_{a 3}}=\frac{8333}{8333+4542}=0.65
$$

and

$$
\overline{13}=0.65(\overline{12})
$$

The lengths of line segments $\overline{12}$ and $\overline{13}$ depend on the scale of the psychrometric chart used. However, when length $\overline{13}$ is laid out along $\overline{12}$ from state 1 , state 3 is accurately determined. If the volume flow rates (cfm) had been used in place of mass flow rates to determine the mixed condition,

$$
\frac{\overline{13}}{\overline{12}}=\frac{2000}{2000+1000}=0.67
$$

and

$$
\overline{13}=0.67(\overline{12})
$$

In turn, this would result in some loss in accuracy in determining the mixed condition.

## Evaporative Cooling

This type of process is essentially adiabatic, and the cooling effect is achieved through evaporation of water sprayed into the airstream. Therefore, the process is most effective when the humidity of the moist air is low. This is often the case at higher elevations and in desert-like regions.

## azar $r^{272}$ asim

The devices used to achieve this process are usually chambers with a sump from which water is sprayed into the airstream, with the excess water being drained back into the sump and recirculated. A small, insignificant amount of makeup water is required. When the makeup water is neglected, the energy equation becomes

$$
\begin{equation*}
h_{1}=h_{2}, \tag{A.37}
\end{equation*}
$$

which leads to the conclusion that the wet-bulb temperature is essentially constant. An evaporative cooling process is shown in Figure A.7. Example A. 5 illustrates the process.

Figure A. 7 Evaporative cooling process.
(Source: Cooling and Heating Load Calculation Principles, Figure D7).

## Example A. 5 Evaporative Cooling

Two thousand cfm of atmospheric air at $100^{\circ} \mathrm{F}$ and $10 \%$ relative humidity are to be cooled in an evaporative cooler. The relative humidity of the air leaving the cooler is $50 \%$. Determine the dry-bulb temperature of the air leaving the cooler, the required amount of makeup water, and the cooling effect. Assume standard sealevel pressure.

Solution: The process is shown in Figure A. 7 and ASHRAE Psychrometric Chart 1 (ASHRAE 1992) can be used to determine the final temperature, the humidity ratios $W_{1}$ and $W_{2}$, and specific volume $v_{1}$ by laying out the line $1-2$. Then

$$
\begin{aligned}
& t_{2}=76^{\circ} \mathrm{F} \\
& W_{1}=0.0040 \mathrm{lb}_{\mathrm{v}} / l \mathrm{~b}_{\mathrm{a}} \\
& W_{2}=0.0095 \mathrm{lb}_{\mathrm{v}} / \mathrm{lb}_{\mathrm{a}} \\
& v_{1}=14.2 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}
\end{aligned}
$$

The flow rate of the make up water is given by Equation A.21:

$$
m_{w}=m_{a}\left(W_{2}-W_{1}\right)
$$

where

$$
\begin{gathered}
m_{a}=60(\mathrm{cfm}) / v_{1}=60(2000) / 14.2=8450 \mathrm{lb}_{\mathrm{a}} / \mathrm{h} \\
m_{w}=8450(0.0095-0.004)=46.5 \mathrm{lb}_{\mathrm{w}} / \mathrm{h}
\end{gathered}
$$

This is a volume flow rate of 0.093 gal of water per minute. The assumption of negligible makeup water is thus valid. Normally, one would use Equation A. 15 to determine the cooling effect or heat transfer rate; however, in this case there is no external heat transfer. There has been an internal transformation of energy where sensible heat from the air has evaporated water, which has become part of the airwater vapor mixture. To evaluate the cooling effect one has to apply the conditioned air to a space to be conditioned. Suppose the air in this example is supplied to a room that is maintained at $85^{\circ} \mathrm{F}$ and $40 \%$ relative humidity.

$$
q=m_{a}\left(h_{r}-h_{2}\right)
$$

and from ASHRAE Psychrometric Chart 1 (ASHRAE 1992),

$$
h_{2}=29.2 \mathrm{Btu} / \mathrm{b}_{\mathrm{a}}
$$

and

$$
h_{r}=31.8 \mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}
$$

then

$$
q=8450(31.8-29.2)=21,970 \mathrm{Btu} / \mathrm{h} .
$$

## Fog Condition

A constant pressure fog condition happens when the cooling process at constant pressure occurs in such a way that water droplets remain suspended in the air in a nonequilibrium condition after the dew point is reached. If all the condensed liquid remains suspended along with the remaining water vapor, the humidity ratio remains fixed. Energy and mass balance equations must be examined.

The fog condition exists when the condition is to the left of the saturation curve on the psychrometric chart, regardless of how that condition was attained. All that is inferred is that liquid water droplets remain suspended in the air rather than dropping out, as required by total equilibrium concepts. This two-phase region represents a mechanical mixture of saturated moist air and liquid water with the two components in thermal equilibrium. Isothermal lines in the fog region are coincident with extensions of thermodynamic wet-bulb temperature lines. As a rule, it is not necessary to make calculations in the fog region.

## Conditioning a Space

Air must be supplied to a space at certain conditions to absorb the load, which generally includes both a sensible and a latent component. In the case of a cooling load, the air undergoes simultaneous heating and humidification as it passes through the space and leaves at a condition dictated by comfort conditions. Such a conditioning process is shown in Figure A.8.

The process 1-2 and its extension to the left are called the condition line for the space. Assuming that state 2 , the space condition, is fixed, air supplied at any state on
the condition line, such as at state 1 , will satisfy the load requirements. However, as the point is moved, different quantities of air must be supplied to the space. In general, the closer point 1 is to point 2 , the more air is required, and the converse is also true.

The sensible heat factor for the process can be determined using the circular scale by transferring a parallel line as shown in Figure A. 8 and is referred to as the room sensible heat factor (RSHF). The RSHF is dictated by the relative amounts of sensible and latent cooling loads on the space. Therefore, assuming that state 2 -the space condition-is known, the condition line can be constructed based on the cooling load. State 1, which depends on a number of factors such as indoor air quality, comfort, and the cooling coil, then completely defines the amount of air required.

## Example A. 6 Air Supply Rate

A given space is to be maintained at $78^{\circ} \mathrm{F} \mathrm{dB}$ and $65^{\circ} \mathrm{F}$ wB. The total cooling load for the space has been determined to be $60,000 \mathrm{Btu} / \mathrm{h}$, of which $42,000 \mathrm{Btu} / \mathrm{h}$ is sensible heat transfer. Assume standard sea-level pressure and compute the required air supply rate.

Solution: A simplified schematic is shown in Figure A.8. State 2 represents the space condition and state 1 , at this point unknown, represents the entering air condition. By Equation A.20, the sensible heat factor is

$$
\text { RSHF }=42,000 /(60,000)=0.7
$$

The state of the air entering the space lies on the line defined by the RSHF on ASHRAE Psychrometric Chart 1 (ASHRAE 1992). Therefore, state 2 is located as shown on Figure A.8, and a line drawn through the point parallel to the RSHF = 0.7 line on the protractor. State 1 may be any point on the line and is determined by the operating characteristics of the equipment, desired indoor air quality, and by what will be comfortable for the occupants. For now, assume that the dry-bulb temperature $t_{1}$ is about $20^{\circ} \mathrm{F}$ less than $t_{2}$. Then, $t_{1}=58^{\circ} \mathrm{F}$ and state 1 is determined. The air quantity may now be found from

$$
q=m_{a}\left(h_{2}-h_{1}\right)=60(\mathrm{cfm})\left(h_{2}-h_{1}\right) / v_{1}
$$

Figure A. 8 Space-conditioning psychrometric process.
(Source: Cooling and Heating Load Calculation Principles, Figure D8).
and

$$
\operatorname{cfm}_{1}=\frac{q v_{1}}{\left(h_{2}-h_{1}\right) 60}
$$

From ASHRAE Psychrometric Chart 1 (ASHRAE 1992), $h_{2}=30$ Btu/ $/ \mathrm{b}_{\mathrm{a}}, h_{1}$ $=23 \mathrm{Btu} / \mathrm{lb}_{\mathrm{a}}$, and $v_{1}=13.21 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$. Thus,

$$
\operatorname{cfm}_{1}=\frac{60,000(13.21)}{(30-23) 60}=1890
$$

Note that the volume flow rate at state 1 is not standard cfm (scfm) but the actual cfm . It is sometimes desirable to give the volume flow rate as scfm. The actual airflow can be easily transformed by multiplying by the ratio of standard specific volume to actual specific volume:

$$
\begin{gathered}
\operatorname{scfm}_{1}=\operatorname{cfm}_{1}\left(v_{s} / v_{1}\right) \\
\operatorname{scfm}_{1}=1890(13.3 / 13.21)=1903
\end{gathered}
$$

In case this problem was being solved for some elevation where a psychrometric chart was not available, Equation A. 12 or A. 13 and Table A. 2 would be convenient. Assume that the elevation is 7500 ft above sea level and find $\mathrm{cfm}_{1}$. From Equation A.12:

$$
q_{s}=60(\mathrm{cfm}) c_{p}\left(t_{2}-t_{1}\right) / v_{1}
$$

The specific volume, $v_{1}=17.608 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$ from Table A. 2 and $c_{\mathrm{p}}=0.244 \mathrm{Btu} /$ $\left(\mathrm{lb}_{\mathrm{a}}{ }^{\circ} \mathrm{F}\right)$ :

$$
\begin{gathered}
\operatorname{cfm}_{1}=\frac{v_{1} q_{s}}{60\left(c_{p}\right)\left(t_{2}-t_{1}\right)} \\
\operatorname{cfm}_{1}=\frac{17.608(42,000)}{60(0.244)(78-58)}=2526
\end{gathered}
$$

## A. 3 Processes Involving Work and Lost Pressure

Air distribution systems have fans to circulate the air to the various conditioned spaces. The work energy or power input to a fan takes two forms as it enters the airstream. First, the useful effect is to cause an increase in total pressure at the fan outlet. The total pressure is the driving potential for the air to flow throughout the system. The second effect is not useful and is due to the inability of the fan to convert all the work input into total pressure, and the result is an increase in the air temperature, the same as if the air was heated. The fan total efficiency relates these quantities:

$$
\begin{equation*}
\eta_{t}=P_{a} / P_{S H} \tag{A.38}
\end{equation*}
$$

where
$P_{a}=$ power delivered to the air, Btu/h or horsepower (hp) $P_{S H}=$ shaft power input to the fan, Btu/h or hp

The shaft power input may be expressed using the energy equation as

$$
\begin{equation*}
P_{S H}=m_{a}\left(h_{2}-h_{1}\right)=m_{a} c_{p}\left(t_{2}-t_{1}\right) \tag{A.39}
\end{equation*}
$$

Since no moisture transfer is present, the power input to the air is

$$
\begin{equation*}
P_{a}=m_{a}\left(P_{01}-P_{02}\right) / \rho_{a}=\eta_{t} P_{S H} \tag{A.40}
\end{equation*}
$$

where
$P_{0}=$ total pressure for the air, $\mathrm{lb}_{\mathrm{f}} / \mathrm{ft}^{2}$
$\rho_{a}=$ air mass density, $\mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$
Combining Equations A. 39 and A. 40 results in

$$
\begin{equation*}
t_{2}-t_{1}=\left(P_{01}-P_{02}\right) /\left(\eta_{t} c_{p} \rho_{a}\right) \tag{A.41}
\end{equation*}
$$

which expresses the temperature rise of the air from the fan inlet to the point where the total pressure has been dissipated. It is assumed that the motor driving the fan is outside the airstream. When standard air is assumed, $\left(p_{01}-p_{02}\right)$ is in in. of water gage and $\eta_{t}$ is expressed as a fraction, so Equation A. 41 reduces to

$$
\begin{equation*}
t_{2}-t_{1}=0.364\left(P_{01}-P_{02}\right) / \eta_{t} \tag{A.42}
\end{equation*}
$$

When the fan motor is located within the airstream, such as with a direct drive fan, $\eta_{t}$ in Equation A. 41 must be replaced with the product of the fan total efficiency and the motor efficiency. Table A. 3 gives the air temperature rise for standard air as a function of fan efficiency and total pressure rise according to Equation A.42. Figure A. 9 illustrates the effect of fans. Process 1-2 is for a draw-through-type fan installation where the air coming off the cooling coil experiences a rise in temperature before entering the space at state 2 . Process $2-3$ represents the space-conditioning process. Process 3-4 would be typical of the effect of a return air fan.

Table A. 3 Air Temperature Rise Caused by Fans, ${ }^{\circ} \mathrm{F}$
(Source: Cooling and Heating Load Calculation Principles, Table D3)

| Fan or Combined* Motor and Fan Efficiency, \% |  | Pressure Difference, in. of Water |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1.0 | 1.5 | 2.0 | 2.5 | 3.0 | 3.5 | 4.0 | 4.5 | 5.0 | 5.5 | 6.0 |
| 50 | 0.7 | 1.1 | 1.5 | 1.8 | 2.2 | 2.6 | 2.9 | 3.3 | 3.6 | 4.0 | 4.4 |
| 55 | 0.7 | 1.0 | 1.3 | 1.7 | 2.0 | 2.3 | 2.7 | 3.0 | 3.3 | 3.6 | 4.0 |
| 60 | 0.6 | 0.9 | 1.2 | 1.5 | 1.8 | 2.1 | 2.4 | 2.7 | 3.0 | 3.3 | 3.6 |
| 65 | 0.6 | 0.8 | 1.1 | 1.4 | 1.7 | 2.0 | 2.2 | 2.5 | 2.8 | 3.1 | 3.4 |
| 70 | 0.5 | 0.8 | 1.0 | 1.3 | 1.6 | 1.8 | 2.1 | 2.3 | 2.6 | 2.9 | 3.1 |
| 75 | 0.5 | 0.7 | 1.0 | 1.2 | 1.5 | 1.7 | 1.9 | 2.2 | 2.4 | 2.7 | 2.9 |
| 80 | 0.5 | 0.7 | 0.9 | 1.1 | 1.4 | 1.6 | 1.8 | 2.1 | 2.3 | 2.5 | 2.7 |
| 85 | 0.4 | 0.6 | 0.9 | 1.1 | 1.3 | 1.5 | 1.7 | 1.9 | 2.1 | 2.4 | 2.6 |
| 90 | 0.4 | 0.6 | 0.8 | 1.0 | 1.2 | 1.4 | 1.6 | 1.8 | 2.0 | 2.2 | 2.4 |
| 95 | 0.4 | 0.6 | 0.8 | 1.0 | 1.2 | 1.3 | 1.5 | 1.7 | 1.9 | 2.1 | 2.3 |
| 100 | 0.4 | 0.6 | 0.7 | 0.9 | 1.1 | 1.3 | 1.5 | 1.6 | 1.8 | 2.0 | 2.2 |

*If fan motor is situated within the airstream, the combined efficiency is the product of the fan and motor efficiencies. If the motor is external to the airstream, use only the fan efficiency.

## Load Calculation Applications Manual (I-P), Second Edition

Figure A. 9 Psychrometric processes showing effect of fans.
(Source: Cooling and Heating Load Calculation Principles, Figure D9).

It should be noted that from, the standpoint of load calculation, all the shaft power input to the fan eventually enters the airstream, because the energy represented by Equation A. 39 is converted to energy stored in the air as the air flows through the ducts and into the space, where total pressure is approximately zero.

## A. 4 Heat Transfer in the Air Distribution System

It is common for some part of the air delivery or return system to be located outside of the conditioned space. Heat transfer to or from the system then has an effect on the psychrometric analysis and the cooling load, much like fans do, as discussed in the previous section. Duct systems should be well insulated to minimize heat loss or gain. Indeed, an economic study would show that well-insulated ducts are very cost effective (ASHRAE 1989). However, in cases of high exposure and large temperature differences, it is desirable to estimate the heat loss/gain and the temperature rise/fall of the airstream. The physical problem is quite similar to a heat exchanger where an airstream flowing through a pipe is separated from still air by an insulated duct.

The following analysis may not always be practical. The intent is to discuss the problem fully so that a designer can adapt to a given situation. Heat transfer to the airstream is given by

$$
\begin{equation*}
q=m_{a}\left(h_{2}-h_{1}\right)=m_{a} c_{p}\left(t_{2}-t_{1}\right) \tag{A.43}
\end{equation*}
$$

and by the heat exchanger equation

$$
\begin{equation*}
q=U A \Delta t_{m} \tag{A.44}
\end{equation*}
$$

where
$U=$ overall heat transfer coefficient, Btu/(h $\left.\cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$
$A=$ surface area of the duct on which $U$ is based, $\mathrm{ft}^{2}$
$\Delta t_{m}=\log$ mean temperature difference, ${ }^{\circ} \mathrm{F}$
When Equations A. 43 and A. 44 are equated and solved for the temperature rise,

$$
\begin{equation*}
t_{2}-t_{1}=\frac{U A \Delta t_{m}}{m_{a} c_{p}} \tag{A.45}
\end{equation*}
$$

some simplifications are in order. Since the anticipated temperature rise is small and the temperature in the surrounding $t_{o}$ is constant,

$$
\begin{equation*}
\Delta t_{m} \approx t_{o}-t_{1} \tag{A.46}
\end{equation*}
$$

As discussed previously,

$$
m_{a}=60(\mathrm{cfm}) / v_{1}
$$

and $c_{p}=0.244 \mathrm{Btu} / \mathrm{lb} \cdot{ }^{\circ} \mathrm{F}$. It is usually most convenient to base $U$ on the inside surface area of the duct, so

$$
\begin{equation*}
U_{i}=\frac{1}{\left(1 / h_{i}\right)+R_{d}\left(A_{i} / A_{m}\right)+\left(1 / h_{o}\right)\left(A_{i} / A_{o}\right)} \tag{A.47}
\end{equation*}
$$

where
$h_{i}=$ heat transfer coefficient inside the duct, $\mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F}\right)$
$h_{o}=$ heat transfer coefficient outside the duct, Btu/(h.ft $\left.{ }^{2} \cdot{ }^{\circ} \mathrm{F}\right)$
$R_{d}=$ unit thermal resistance for the duct and insulation, $\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right) / \mathrm{Btu}$
$A_{i}=$ duct inside surface area, $\mathrm{ft}^{2}$
$A_{o}=$ duct outside surface area, $\mathrm{ft}^{2}$
$A_{m}=$ duct mean surface area, $\mathrm{ft}^{2}$
Again simplifications are in order. The outside heat transfer coefficient $h_{o}$ will be about 1.5 to $2.0 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2}{ }^{\circ} \mathrm{F}\right)$, depending on whether the insulation is foil-backed or not. The mean area $A_{m}$ can be approximated by

$$
\begin{equation*}
A_{m} \approx\left(A_{i}+A_{o}\right) / 2 \tag{A.48}
\end{equation*}
$$

The thermal resistance of metal duct can be neglected and only the insulation considered. For standard air, the inside heat transfer coefficient $h_{i}$ can be approximated by a function of volume flow rate and duct diameter with

$$
\begin{equation*}
h_{i}=7.64(\mathrm{cfm})^{0.8} / D^{1.8} \tag{A.49}
\end{equation*}
$$

where $D$, the duct diameter, is in inches.
In the case of rectangular duct, Equation A. 49 will be adequate when the aspect ratio is not greater than about $2: 1$. When duct velocity is compatible with typical low velocity duct design, $h_{i}$ will vary from about 15 to $30 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$ as cfm varies from 200 to 35,000 .

## Example A. 7 Duct Losses

Two thousand cfm of air flows in a 16 in . diameter duct 100 ft in length. The duct is metal with 2 in. of fibrous glass insulation and is located in an uncontrolled space where the air temperature is estimated to be $120^{\circ} \mathrm{F}$ on a design day. Estimate the temperature rise and heat gain for air entering the duct at $60^{\circ} \mathrm{F}$, assuming standard air conditions.

Solution: Equations A. 43 and A. 45 may be used to solve this problem. The various parameters required are evaluated as follows:

$$
\begin{gathered}
\Delta t_{m} \approx t_{o}-t_{1}=120-60=60^{\circ} \mathrm{F} \\
m_{a}=60(2000) / 13.3=9023 \mathrm{lb}_{\mathrm{a}} / \mathrm{h}
\end{gathered}
$$

where
$v_{1}=13.3 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{a}}$, for standard air
$A_{i}=\pi(16 / 12)=4.2 \mathrm{ft}^{2} / \mathrm{ft}$
$A_{o}=\pi(20 / 12)=5.2 \mathrm{ft}^{2} / \mathrm{ft}$
$A_{m}=\left(A_{\mathrm{i}}+A_{\mathrm{o}}\right) / 2=4.7 \mathrm{ft}^{2} / \mathrm{ft}$
$h_{o}=2.0 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$
$R_{d}=7\left(\mathrm{~h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right) / \mathrm{Btu}$
$h_{i}=7.64(2000)^{0.8} /(16)^{1.8}=22.7 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$ Then the overall heat transfer coefficients $U_{i}$ may be computed:

$$
U_{i}=\frac{1}{(1 / 22.7)+7(4.2 / 4.7)+(1 / 2)(4.2 / 5.2)}=0.15 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)
$$

It should be noted that the insulation is the dominant resistance; therefore, the other thermal resistances do not have to be known with great accuracy. In fact, the inside and outside thermal resistance could be neglected and $U_{i}=0.16 \mathrm{Btu} /\left(\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}\right)$.

The temperature rise is then given by Equation A.45:

$$
t_{2}-t_{1}=\frac{100(4.2)(0.15)(60)}{0.244(9023)}=1.72^{\circ} \mathrm{F}
$$

And the heat gain to the air from Equation A. 43 is:

$$
q=0.244(9023)(1.72)=3780 \mathrm{Btu} / \mathrm{h}
$$

which is sensible heat gain.

The previous example shows that it is generally unnecessary to compute the heat transfer coefficients $h_{i}$ and $h_{o}$ when the duct is well insulated. If the duct is not insulated or poorly insulated, the complete calculation procedure is necessary to obtain reliable results.

## Appendix B <br> Spreadsheet Implementation of the RTSM

Many approaches could be taken to implement the radiant time series method (RTSM) in a spreadsheet, depending on how the conduction time series factors (CTSFs) and radiant time factors (RTFs) are provided. For example, the RTSM could rely on pretabulated CTSFs and RTFs. Or it could rely on a separate computer program to generate custom CTSFs and RTFs. The implementation presented here instead relies on the Visual Basic for Applications (VBA) programming language that is embedded in Microsoft ${ }^{\circledR}$ Excel ${ }^{\circledR}$. Programs for generating both CTSFs and RTFs are included with the sample spreadsheet $B-1 \_R T S M . x l s$ included in the online supporting files accompanying this manual (available at www.ashrae.org/lcam).

This chapter first gives an overview of the spreadsheet features (Section B.1), then presents an in-depth example of using the spreadsheet to compute the cooling loads for the office analyzed in Chapter 8 (Section B.2). Here, the spreadsheet will be used to automatically compute cooling loads for multiple months. Following the example presented in Section B.2, Sections B. 3 to B. 7 serve as a reference guide for the spreadsheet, defining input parameters, intermediate values, and results.

## B. 1 Overview

Basic features of the spreadsheet implementation of the RTSM procedure are described briefly as follows:

- A master input worksheet holds values of input parameters that are reasonably likely to stay constant for all or many zones in a building (e.g., location, design temperatures, lighting densities, etc.)
- A single worksheet is used for each zone. Each worksheet includes a range for zone input parameters, intermediate results, and monthly design day hourly cooling loads. Multiple zones can be represented by individual sheets in a workbook.
- The worksheets are designed in such a way that they can be used for a single design day analysis or automated computation of cooling loads for design days for each month of the year. The annual peak cooling loads for the building and individual zones are determined automatically.
- The CTSFs and RTFs are computed for each zone, in each worksheet, at the beginning of the load calculation by marching through each zone worksheet. The CTSFand RTF-generating subprogram reads the input parameters from each spreadsheet and generates the coefficients by calling the VBA subprocedures.

Surface geometry and construction information:

- Construction surfaces require a keyword for identification of the type of constructions: wall for exterior and partition walls, roof for roofs, floor for floors, and window for windows. These keywords are used in the subprograms for collecting heat gains and cooling load contributions for each type of surface.
- A surface description includes geometric parameters for each surface: facing direction, tilt angle, and surface area. Inside surface conductances depend on the tilt angle of the surface; solar irradiation and sol-air temperatures depend on facing direction and tilt angle. The area is needed for many calculations.

## Load Calculation Applications Manual (I-P), Second Edition

- Inside surface longwave emissivity/absorptance is used in the RTF generation procedure for determining distribution and surface-to-surface interchange of longwavelength radiation.
- Outside surface shortwave absorptance is used for sol-air temperature calculation.
- Two types of boundary conditions are used as identification keywords: TOS is used for outside boundary conditions, and $T A$ is used for inside boundary conditions. For windows, the keyword TOS and the keyword Window (in the Surface Type row) are used to identify the surface and impose outdoor air temperature as the outside boundary condition.
- The number of layers includes the total number of layers for each surface, including the inside and outside surface film conductances. The layers are specified in order from outside to inside.
- This implementation expects the zone model to use one type of fenestration. A single normal solar heat gain coefficient (SHGC) is defined for all windows in a zone. Angular dependency of the SHGC is determined using tabulated angle correction factors and the normal SHGC internally in the subprogram. The reference FENCLASS angle correction factors are tabulated in a worksheet named SHGCNEW.

Weather information:

- The spreadsheet incorporates the ASHRAE design day weather database and allows users to select from thousands of locations around the world. The available data come from the same source as the PDFs on the accompanying online files. The master input worksheet uses an Excel function to select a location and then retrieve the monthly design weather data automatically for the master input worksheet. Each zone design day weather data cell location is linked to this master input worksheet range. However, for other locations, these equations may be overridden.

## B. 2 Office Example— RTSM Spreadsheet

This section presents a detailed example of use of the RTSM with a spreadsheet that supports building-level default inputs, multiple zones, and automated multimonth calculations. The office used as an example in Chapter 8 is revisited here.

## Building Inputs

The spreadsheet implementation of the RTSM is included in the online supporting files accompanying this manual as $B-1 \_R T S M . x l s$. It has been organized so that much of the building-related data are entered on a worksheet called MASTER INPUT, as shown in Figure B.1. This information is then propagated to the individual zone worksheets. If necessary, the individual zone worksheets can be edited so that they do not take all of their information from the master input worksheet. For example, different zones may have different heat gain schedules; those schedules can be changed on the individual zone worksheets.

The worksheet has been color-coded-most users should be first concerned with entering the information in the cells that are shaded and have a black font. Unshaded cells with a black font are default settings that advanced users might wish to change. Cells with a red font are automatically filled in when other settings are chosen. For example, choosing the location from the library will set the latitude, longitude, and other parameters. A user would only need to change these values if choosing a location that is not in the library.

With the above in mind, building data can now be entered into the master input worksheet. Although any order can be followed, in this example we will enter the unit system, location data, inside design conditions, internal heat gain data, fenestration data, and miscellaneous data.

## Unit System

The unit system—inch-pound (I-P) or international system (SI)—is something that should be set at the beginning; the default is I-P units. This is set by simply typing IP or $S I$ in cell C26. Changing from one unit system to the other will result in location information, if chosen from the location library, changing units correctly (i.e., the design temperatures will change correctly from one set of units to the other). However, other user entries, such as internal heat gains and building dimensions, will keep the same numeric value. This example will use I-P units.

## Location Data

There are two ways to enter location data-either use the library of locations from the dropdown menu (covering cells B4 through D4) or enter the data manually. The first method is by far the easiest, but in the event that the user wishes to use a location not available as part of the database, manual entry is required. Figure B. 2 shows the location dropdown menu being used to select Atlanta Municipal design conditions. In conjunction with the location, the user must select the $0.4 \%, 2 \%, 5 \%$, or $10 \%$ design condition from the dropdown box in cell C6. Selecting the location and design conditions sets the latitude (C11), longitude (C12), time zone (C13), altitude (C27), and corresponding

Figure B. 1 The master input worksheet.

Figure B. 2 Location selection from the location library.
barometric pressure (C28). It also sets the monthly design dry-bulb temperature, mean coincident wet-bulb temperature, daily ranges, and optical depths in cells F10:K21. The spreadsheet is set to automatically calculate peak cooling loads for every month, so the month input (C12) is usually not needed.

Note that the selected weather conditions are the monthly design conditions, not the annual design conditions. For example, Atlanta 5\% represents a collection of weather data. For each month, the value given represents the $5 \%$ cumulative frequency of occurrence for that month. The Atlanta July 5\% condition gives a peak dry-bulb temperature of $91.9^{\circ} \mathrm{F}$. The Atlanta annual $1 \%$ condition gives a peak dry-bulb temperature of $91.7^{\circ} \mathrm{F}$. For this example, we will use the Atlanta 5\% monthly design conditions.

If a location that is unavailable in the location library is needed, the user may input the data manually. This would involve entering inputs in the relevant cells that would replace the VLOOKUP functions that extract data from the location library.

## Indoor Design Conditions

Selection of indoor design conditions was discussed briefly in Chapter 4. Here, we will choose $75^{\circ} \mathrm{F}$ and $50 \%$ relative humidity. These are set in cells M11 and N11.

## Internal Heat Gains and Schedules

Information about internal heat gains and schedules may be set in cells N15:O22 and C37:E60, respectively. These might be thought of as default values for the zones in the building. Peak heat gain rates and schedules are quite likely to vary throughout the building, but entering the information here on a per-unit-area basis will give a default setting for all zones that can be changed as needed.

People are specified on an area-per-person basis coupled with sensible and latent heat gain per person. Here, we will set the peak occupancy to $130 \mathrm{ft}^{2}$ per person, with each person having a sensible heat gain of $250 \mathrm{Btu} / \mathrm{h}$ and a latent heat gain of $200 \mathrm{Btu} / \mathrm{h}$. This corresponds to moderately active office work adjusted for a typical male/female ratio, as shown in Table 6.1. This peak occupancy rate is then adjusted on an hour-byhour basis according to the schedule of fractions in cells C37:C60.

Peak lighting and equipment heat gains are specified in cells N19, N21, and N 22 on a watt-per-square-foot basis. Lighting heat gain has been set at $0.846 \mathrm{~W} / \mathrm{ft}^{2}$ and equipment sensible heat gain has been set at $1 \mathrm{~W} / \mathrm{ft}^{2}$. We have assumed no equipment latent heat gain, as would be expected for office equipment. Like occupant heat gains, the peak values are modified by the fractional schedules given in cells D37:E60.

In addition to setting peak heat gain levels and schedules for each heat gain type, the radiant and convective fractions are set for each heat gain type. From Table 6.1, the occupant sensible heat gain is taken as $60 \%$ radiative. For pendant lighting, a value of radiative fraction, $57 \%$, is chosen from Table 6.3. For equipment, it is anticipated that there will be a range of office equipment, fan-cooled and non-fan-cooled. Taking an intermediate value between the two options ( $10 \%$ radiative for fan-cooled, $30 \%$ radiative for non-fan-cooled) given in Table 7.10, we choose 15\% radiant. These selections are shown in Figure B.3.

People, lighting, and equipment schedules are set in cells C37:E60. For purposes of making the load calculation, some reasonable assumptions must be made about the schedule of operation. Here, we have assumed that the building will be fully in operation from about 7:30 a.m. to $5: 30 \mathrm{p} . \mathrm{m}$. and, as a result, the people, lighting, and equipment fractions are set to be 1 for hours $9-17$ and 0.5 for hours 8 and 18. During the remainder of the day, it is assumed that there will be no occupants present but that lighting and equipment will have about $10 \%$ of their peak heat gain due to some lights and equipment remaining on and/or being in standby condition.

## Fenestration Details

The windows have a normal SHGC of 0.49 ; this is set in cell O25. Initially, we will assume no interior shading, so the interior attenuation coefficients (IACs), set in cells Q33:Q35, are 1, and the radiative fraction is $100 \%$. Based on the example in Chapter 8, the closest fenestration type is 5 D ; this is selected with the dropdown menu near cell P26. This has the effect of setting the SHGC in cell O25 and the SHGC angle correction factors shown in cells K30:K36.

Internal shading is set in the dropdown boxes near cells M31:Q32. After choosing a new fenestration type, the shading type will initially be "no shading"; then, using the dropdown menu, other internal shading options can be set as shown in Figure B.4. Choosing a shading option sets the IACs and radiative fraction in cells Q33:Q36.

## Fraction to Return Air

Finally, there are two additional cells that are used to set estimates of the fraction of heat gains that go directly to the return air from lighting and, for the second floor, the roof. For lighting, the fraction to return air is taken from

Figure B. 3 Internal heat gain inputs on master input worksheet.

Table 6.3, where $100 \%$ of the lighting heat gain due to pendant luminaires is estimated to go to the room. For the roof heat gain, the actual percentage that goes to the return air depends on the surface and return air temperatures-quantities that cannot readily be determined by the RTSM alone. Therefore, an estimate of $30 \%$ is made here. As shown in Section 8.5, it is possible to make an estimate using a relatively simple, quasi-steady-state heat balance. Those results suggest that the percentage of roof heat gain that goes to the return air should be close to $80 \%$. However, we will use $30 \%$ here for consistency with Section 8.3.

In the spreadsheet, if the user clicks on the Zone 1 tab, the worksheet shown in Figure 8.11 will be shown. In the first 23 rows shown in Figure B.5, almost all of the information is taken directly from the master input worksheet. One exception is the infiltration information, found in cells F10:F14. Here, the zone ceiling height, floor area, and ACH are entered in order to determine the infiltration rate.

In some cases, not all of the input derived from the master input sheet will be suitable, in which case the data from the master input sheet can be manually overridden by simply typing in a new value.

However, as shown in Figure B.4, some of the inputs, particularly the occupancy, may not be suitable for a conference room. It is expected that the peak occupancy loading will be more than 1.9 people. As an estimate, consider a peak occupancy load of 12 people. To override the information taken from the master input worksheet, simply enter the number 12 in cell J8.

AIR CONDITIONING COMPANY

Scrolling down, as is shown in Figure B.6, all of the information is input for each surface:

- Surface ID (spreadsheet row 25) is an index number used to keep track of each surface.
- Surface Name (row 26) is for the user's use in identifying each surface.
- Surface Type (row 27) is used for identifying the heat gain types when summing different categories of heat gain and for identifying whether sol-air temperature (for opaque surfaces) or air temperature (for windows) is used as the outside boundary condition.

Figure B. 4 Fenestration and shading inputs.

Figure B. 5 Zone input as derived from the master input worksheet.

AIR CONDITIONING COMPANY

Figure B. 6 Zone input-the surface details.

- Facing Direction (row 28) is the direction the outside of the surface faces, in degrees clockwise from north.
- Tilt Angle (row 29) is the degrees the angle is tilted above horizontal; a horizontal surface would have a tilt angle of $0^{\circ}$; a vertical surface would have a tilt angle of $90^{\circ}$.
- Area (row 30) is the surface area in square feet or square meters.
- Emissivity In (row 31) is the emissivity/absorptivity of the surface on the inside for thermal (longwave) radiation. This is used in RTF generation.
- Sol Abs. Out (row 32) is the absorptivity of the surface on the outside to solar radiation. This entry is ignored for windows.
- Boundary Condition (row 33) indicates whether the surface is an interior or exterior surface. If it is an interior surface, its properties are only used for computing RTFs. If it is an exterior surface, its properties are used both for computing RTFs and for computing heat gains.
- Number of Layers (row 34) indicates how many layers of material will be specified in rows 35-44.
- For windows, the Window Height and Window Width (rows 47 and 48) are needed in order to compute the shading. The horizontal projection and vertical projection dimensions in rows 50-54 correspond to Figure D. 2 in Appendix D of this manual.

With general inputs for the building entered on the master input worksheet and zone-specific inputs entered on the Zone 1 input sheet, it is possible to perform a cooling load calculation for the office. Figure B. 7 shows two buttons that will perform cooling load calculations:

Figure B. 7 The master input worksheet showing buttons for cooling load calculations.

- Annual Building Cooling Load will perform a cooling load calculation for all zones for all months of the year.
- Monthly Building Cooling Load (Select Month) will perform a cooling load calculation for all zones for the month specified in cell C14.

Setting the month in cell C14 to 7 (July) and clicking the Monthly Building Cooling Load button results in a cooling load calculation for the month of July. Returning to the Zone 1 worksheet and scrolling down from the input section, the reader can see the intermediate calculations, starting with beam radiation and diffuse radiation incident on each surface, as shown in Figure B.8. The reader can inspect the spreadsheet equations-Figure B. 8 shows one of the equations for finding the beam radiation incident on a surface. The Solar_Beam function is VBA code and the reader can see this code too. (In Excel 2003, this is done from the Tools menu by choosing Macro, then Visual Basic Editor. In Excel 2013, this is done by choosing the Developer tab, then the Visual Basic icon. In Excel 2013, the Developer tab is not shown by default, so the user must first choose the options button from the File tab, choose Customize Ribbon and check Developer under the list of Main tabs. Open the module Solar then scroll down or search to find the function Solar_Beam, as shown in Figure B.9).

Figure B. 8 The Zone 1 worksheet that shows the beginning of the intermediate calculations.

Scrolling down further in the spreadsheet, one can follow all of the steps of the RTSM procedure:

1. Compute beam (rows $67: 90$ ) and diffuse (rows $94: 117$ ) incident radiation on each surface.
2. Compute sol-air temperature for each surface (rows 121:144).
3. Determine U-factor (row 148) and CTSFs for each construction (rows 149:172). The CTSFs are calculated by VBA subroutines that execute when one of the cooling load calculation buttons is pressed. The CTSFs are written directly to these cells by the VBA code.
4. Conduction heat gains are calculated (rows 178:201).
5. For windows, determine sunlit area fraction (rows 205:228).
6. For windows, determine beam (rows $233: 256$ ) and diffuse (rows 261:284) solar heat gains.

Appendix B: Spreadsheet Implementation of the RTSM

Figure B. 9 Visual basic editor showing Solar_Beam function in solar module.
7. Based on user-defined schedules and peak heat gains, find hourly sensible and latent internal heat gains (rows 290:313).
8. Determine hourly infiltration loads (rows 319:342).
9. Sum heat gains from different types of surfaces (e.g., walls) and split all heat gains into radiative and convective portions (rows 348:371).
10. Compute solar and nonsolar RTFs (rows 375:398). Like the CTSFs, they are calculated by VBA subroutines and written directly to the appropriate cells.
11. Apply the RTFs to the radiant heat gains and compute cooling loads due to radiant and convective heat gains (rows 403:428).
12. Sum all cooling loads on a component basis and find sensible and latent totals for each hour (rows 433:456).

The end results, as they appear in the spreadsheet, can be seen in Figures B. 10 and B.11.

It is entirely possible, though, that the peak cooling load will not occur in July. To examine this possibility, the spreadsheet's other cooling load button (Annual Building Cooling Load) will calculate the cooling loads for 12 monthly design days. It will automatically write 1,2 , etc. in cell C12 of the master input worksheet and calculate the cooling loads for each month. For each day that the cooling load calculation is performed, it will perform the same 11 -step procedure described above, writing into the same cells. When it is done, rows 67:456 will have the loads and intermediate variables for the last month calculated, which is December. For each month, the cooling load components and totals will be given in rows 464:751. The

Figure B. 10 Cooling loads for July design day, first part.
month and hour with the highest zone sensible cooling load will be summarized in row 757, as shown in Figure B.13. In addition, rows $72: 359$ of the master input worksheet contain totals for all zones analyzed, and the peak cooling load for the entire building is found in row 365 .

As may be noted from Figure B.13, the peak sensible cooling load for the office does not occur in the hottest month (July), but rather in September; the difference is about $10 \%$. A check of row 365 of the master input worksheet shows that the building (at this point, really only three zones, not the entire building) has its peak cooling load occurring in July. So, were these three zones representative of the entire building, it would be likely that the equipment would be sized based on July loads. But, the airflow to the office would be sized based on the September peak. The user should be aware, though, that the differences can be more sizable, and zone peak cooling loads can occur in any month of the year.

## B. 3 Description of Input Parameters

Before describing the individual parameters, it should again be noted that the entire spreadsheet can operate in I-P or SI units. This is controlled by entering either $I P$ or $S I$ in cell C26 of the master input worksheet. All other unit-dependent inputs are interpreted based on this cell.

Figure B. 11 Cooling loads for July design day, second part.

Figure B. 12 Zone sensible cooling loads for July 21.

Figure B. 13 Summary of peak cooling load, which occurs in September.

## B.3.1 Master Input Worksheet Parameters

Tables B. 1 to B. 8 describe or define the input parameters in the master input worksheet, giving the cell locations, and a brief note on the use and, in some cases, the source of the data.

## B.3.2 Input Parameters in the Zone Sheets

All of the input parameters described in the master input worksheets are passed directly to the zone sheets by linking the corresponding cells in the zone worksheet to the master input worksheet cell locations. IMPORTANT: These values can be overridden at the zone level by replacing the equation link to the master input worksheet with the actual value. The cell locations for these parameters in the zone sheets are not necessarily the same as in the master input worksheet. The zone-specific input parameters such as the zone geometry, orientations, construction fabrics, and window geometries are specified in each zone. The descriptions of the input parameters are outlined in Tables B.9-B.19.

## B. 4 Intermediate Results on Zone Worksheets

The intermediate results that appear in the zone worksheets are described briefly in Tables B.20-B.22.

## B. 5 Results: Zone Design Day Cooling Load

The hourly cooling loads for each design day and for each zone are summarized on the zone worksheet, as summarized in Table B.23. The zone cooling loads are summarized for the 24 hourly values of the design day. The hourly values are summarized by heat gain type.

## B. 6 Results: Zone Monthly-Hourly Cooling Loads

When all 12 months are run, the zone hourly cooling loads given in Table B. 23 are summarized for each of the 12 months, making a total of 288 hourly values, as shown in Table B.24. Then the zone peak cooling is determined by selecting the
maximum value of the 288 hourly cooling loads. The cooling load components corresponding to the zone peak cooling load are summarized in the zone worksheets in the cell range A757:U757.

Table B. 1 Site: Location and Design Weather Conditions

| Parameter | Cell | Units | Description and Notes |
| :---: | :---: | :---: | :---: |
| Latitude | C11 | degrees | Local latitude: northern hemisphere positive, southern hemisphere negative |
| Longitude | C12 | degrees | Local longitude: west of the prime meridian, positive; east of the prime meridian, negative |
| Time zone | C13 | hours | Standard time zone of the location: hours west of GMT positive, hours east of GMT negative. Example: Atlanta is in NAE, 5 hours west of GMT; the value of the time zone parameter is 5 |
| Month | C14 | - | Month of the year: Jan. $=1$, Feb $=2, \ldots$ |
| Day of month | C15 | - | Design day of the month (default 21) |
| Daylight savings | C16 | - | 1: Daylight savings time is used at this location. 0 : Daylight savings time is not used at this location. |
| Ground reflectance | C18 | - | Reflectance of the ground, see Table D. 2 |
| Design dB temperature | C19 | ${ }^{\circ} \mathrm{F}\left({ }^{\circ} \mathrm{C}\right)$ | Peak design day temperature of the month |
| Design wB temperatures | C20 | ${ }^{\circ} \mathrm{F}\left({ }^{\circ} \mathrm{C}\right)$ | Mean coincident wet-bulb temperature of the month |
| Daily range | C21 | ${ }^{\circ} \mathrm{F}\left({ }^{\circ} \mathrm{C}\right)$ | Design daily dry bulb temperature range of the month |
| taub | C22 | - | Clear-sky optical depth for beam irradiance |
| taud | C23 | - | Clear-sky optical depth for diffuse irradiance |
| $\mathrm{h}_{\text {out }}$ | C24 | $\begin{gathered} \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \\ \left(\mathrm{~W} / \mathrm{m}^{2} \cdot \mathrm{~K}\right) \end{gathered}$ | Outside surface combined conductance, Table 3.4 |

| Convective fraction | P19 | \% | Convective fraction lighting heat gain |
| Equipment |  |  |  |
| Sensible heat gain rate | N21 | $\mathrm{W} / \mathrm{ft}^{2}\left(\mathrm{~W} / \mathrm{m}^{2}\right)$ | Equipment peak sensible heat gain |
| Latent heat gain rate | N22 | $\mathrm{W} / \mathrm{ft}^{2}\left(\mathrm{~W} / \mathrm{m}^{2}\right)$ | Equipment peak latent heat gain, Chapter 6 |
| Radiant fraction | O21 | \% | Radiant fraction of equipment sensible heat gain, Chapter 6 |
| Convective fraction | P21 | \% | Convective fraction equipment sensible heat gain, Chapter 6 |

## B. 7 Results: Building Monthly-Hourly Cooling Loads

Building cooling loads, summed for all zones, for each hour of each monthly design day are summarized, by heat gain component, in the master input worksheet. The 288 hourly total zone cooling loads are added component by component to determine the building monthly-hourly cooling loads summary as shown in Table B. 25 .

Table B. 7 Fenestration Solar Heat Gain

| Parameter | Cell | Units | Description and Notes |
| :--- | :---: | :---: | :---: |
| Normal solar heat gain coefficient (SHGC) | O25 | - | SHGC at zero incidence angle |

Table B. 17 Internal Heat Gain Schedules

| Parameter | Cell | Units | Description and Notes |
| :--- | :---: | :---: | :---: |
| People schedule | C290:C313 | - | Hourly people occupancy fraction |
| Lighting schedule | F290:F313 | - | Hourly lighting use fraction |
| Equipment schedule | H290:H313 | - | Hourly equipment use fraction |

Table B. 18 Zone Geometry, Surface Construction, and Properties

| Parameter | Cell | Units | Description and Notes |
| :---: | :---: | :---: | :---: |
| Surface ID | C26:V26 | - | Zone surface number, assigned sequentially, starting with 1 |
| Surface type | C27:V27 | - | Name of surfaces: the following key words are utilized: wall for exterior and internal surfaces, window for fenestrations, roof for roofs, floor for floor, and furniture for furnishings |
| Facing | C28:V28 | degrees | Surface facing direction measured clockwise from north |
| Tilt angle | C29:V29 | degrees | Surface tilt angle from the horizontal |
| Area | C30:V30 | $\mathrm{ft}^{2}\left(\mathrm{~m}^{2}\right)$ | Surface area |
| LW emissivity in | C31:V31 | - | Inside surface emissivity/absorptivity |
| SW absorption out | C32:V32 | - | Outside surface absorptance to shortwave radiation, (i.e., solar) |
| Boundary conditions | C33:V33 | - | Boundary conditions: TOS for exterior surfaces, $T A$ for partition surfaces. The key difference is that TOS surfaces are used both for computing the response of the zone and for computing net heat gain to the zone. $T A$ surfaces are only used for computing the response of the zone-they store and release energy but have no net heat gain. |
| Number of layers | C34:V34 | - | Number of layers in each construction including the inside and outside combined conductance |
| Layer code | C35:V44 | - | Surface construction layers code. To be selected from the worksheets Layers IP or Layers SI for I-P and SI units, respectively. See Table 7.5. Users may add their own construction layer codes into the spreadsheet worksheets Layers IP and Layers SI. New layers may be entered there with a layer code of no more than three characters-letters and numbers only. |

## Appendix C <br> Calculation of CTSFs and RTFs

This appendix briefly describes the calculation of conduction time series factors (CTSFs) and radiant time factors (RTFs). Only a brief description of the procedures is given here. For details, the reader is referred to the original papers by Spitler and Fisher (1999) and Nigusse (2007) for CTSF generation and Nigusse (2007) for RTF generation using a reduced heat balance method (HBM).

## C. 1 CTSF Generation

The CTSFs are normalized periodic response factors. That is, they are equivalent to the periodic response factors defined by Spitler et al. (1997) divided by the U-factor of the construction. In the 2001 and 2005 editions of the ASHRAE Handbook-Fundamentals (ASHRAE 2005), they were referred to as conduction time factors. In order to reduce ambiguity for the acronym CTF, the term conduction time series factor (CTSF) has been adopted.

Periodic response factors (PRFs) can be generated by converting tabulated or otherwise-computed CTF coefficients (Spitler and Fisher 1999), using a frequency response regression method (Chen and Wang 2005) or using a one-dimensional numerical method (Nigusse 2007). For this manual, a one-dimensional implicit finite volume method (FVM) has been implemented in visual basic for application (VBA). The FVM routines use six uniform control volumes per layer with a fixed 60 -second time step. The periodic response factors are generated by exciting the construction with a unit triangular temperature pulse and computing the resulting heat flux until the response drops below a set limit. The hourly response factors are changed into periodic response factors by summing the corresponding terms as described by Spitler et al. (1997). Then the PRFs are converted to CTSFs by dividing by the U-factor. For further details, see Nigusse (2007).

## C. 2 CTSF Generation-Spreadsheet Implementation

In the spreadsheet $C-1 \_$CTSFgen.xls, included in the supporting files accompanying this manual (online at www.ashrae.org/lcam) and shown in Figure C.1, the user enters the layer codes, from outside to inside, in Cells B5:B14. The spreadsheet comes with thermal properties of the material layers from Table 7.5, but the reader may add more to either the sheet LAYERS IP or the sheet LAYERS SI. Both sheets have a button that will translate and copy the layers from one sheet to the other sheet. The actual computation is done in SI units; users entering in LAYERS IP should click on the button to translate and copy their layers to the other worksheet.

Once the layers are entered, clicking on the GENERATE CTSF button will cause the spreadsheet to calculate the CTSFs and U-factors, and the CTSFs will be plotted as shown in Figure C.2.

## C. 3 RTF Generation

As part of ASHRAE RP-1326 (Spitler 2009), a reduced heat balance procedure was developed to generate RTFs. This algorithm has been implemented in the radiant time series method (RTSM) spreadsheets used in Chapters 7 and 8. The RTF coefficients are determined by exciting the thermal zone model with a

Figure C. 1 CTSF generation spreadsheet inputs.
radiant pulse and monitoring the resulting cooling loads. Solar and nonsolar RTFs are obtained by adjusting the distribution of the radiant pulse. Full details may be found in Nigusse (2007). The spreadsheet C-2_RTFgen.xls implements this algorithm in VBA code.

## C. 4 RTF Generation-Spreadsheet Implementation

This section describes a spreadsheet implementation of the RTF generation procedure. This may be considered an excerpt from the full RTSM spreadsheets discussed in Chapter 8 and Appendix B. Therefore, the inputs are similar to what is described in Chapter 8 and Appendix B. The following input information is required:

1. A zone description consisting of geometric parameters: tilt angles, facing directions, and surface areas.
2. Construction information: layer codes for each material layer in each construction. Additional layers can be specified in the LAYERS IP and LAYERS SI spreadsheets, as discussed above, for the CTSF generation spreadsheet.

The spreadsheet in Figure C. 3 (C-2_RTFgen.xls) shows the input data for the RTF generation. These input parameters are described in the previous section. Clicking the GENERATE RTF button calls the VBA subroutines to read the input parameters, compute the solar and nonsolar RTFs, and return them to the worksheet as shown in Figure C.4.

Figure C. 2 CTSFs generated by spreadsheet.
The user can add more surfaces to the zone in columns $\mathrm{M}, \mathrm{N}$, etc. by following the format in columns C:L. Currently, only 20 surfaces per zone are allowed, though that limit could be changed in the VBA code. Notes on input, also relevant to adding additional surfaces, are as follows:

1. Surface ID numbers should be assigned sequentially.
2. Surface name is at the discretion of the user.
3. Facing angle is degrees clockwise from north.
4. Tilt angle is degrees above horizontal.
5. Surface area is in square feet (I-P) or square meters (SI).
6. Longwave emissivities are used to estimate radiation distributions.
7. All boundary conditions should be set to $T A$.
8. The number of layers, including surface conductances, should be set. Then, in the following rows, layers are specified from the outside to the inside.

Additional layers can be added into the LAYERS IP or LAYERS SI worksheets. Then, using the unit conversion button, the layers for the other worksheet will be synchronized.

## Appendix D <br> Solar Radiation and Heat Gain

This appendix briefly describes the calculation of solar irradiation (solar radiation flux) and sol-air temperature under clear-sky conditions. It is essentially a synopsis of the calculation procedures given in Chapter 14 of the ASHRAE Handbook-Fundamentals (2013). (Chapter 14 of the Handbook covers the subject in more detail, and the reader is referred to this chapter for a more thorough treatment.)

Solar irradiation incident on a surface is of interest for determining heat gains of fenestration in both the radiant time series method (RTSM) and the heat balance method (HBM). For the HBM, it is also used directly as part of the surface heat balance. For the RTSM, it is used to calculate sol-air temperature. The first step in determining solar irradiation incident on a surface is to determine the relevant angles, as described in Section D.1. With these angles determined, the revised ASHRAE clearsky model (Thevenard 2009) can be used to calculate the incident solar irradiation, as shown in Section D.2. If exterior shading devices are present, the reduction in direct or beam irradiation must be determined as explained in Section D.3. Finally, if needed, sol-air temperatures can be determined as described in Section D.4.

## D. 1 Solar Angle Calculations

The earth's rotational position relative to the sun can be characterized with the apparent solar time (AST) (the sun is due south or due north at an AST of noon). The AST will be different from the local time at most locations for several reasons:

- When daylight saving time is in effect, the local standard time (LST) is one hour behind (or one hour less) than the local daylight saving time.
- LST is determined for the standard meridian in each time zone (Eastern Standard Time corresponds to the $75^{\circ} \mathrm{W}$ meridian, Central Standard Time corresponds to the $90^{\circ} \mathrm{W}$ meridian, Mountain Standard Time corresponds to the $105^{\circ} \mathrm{W}$ meridian, and Pacific Standard Time corresponds to the $120^{\circ} \mathrm{W}$ meridian). In general, the local standard meridian corresponds to the number of hours that the time zone is different from coordinated universal time (UTC), multiplied by $15^{\circ}$. The U.S. Central standard time zone is six hours behind UTC; the standard meridian is $-6 \cdot 15^{\circ}=-90^{\circ}$. Likewise, the Central European Time zone is one hour ahead of UTC; the standard meridian is $1 \cdot 15^{\circ}=15^{\circ}$.
- The earth's orbital velocity varies slightly throughout the year, and the resulting difference in rotational position is given by the equation of time (ET). The ET (in minuites) can be read from Table D. 1 for the twenty-first day of each month, or it can be related to the day of the year $n$ by

$$
\begin{gather*}
\mathrm{ET}=2.2918[0.0075+0.1868 \cos (\Gamma)-3.2077 \sin (\Gamma)  \tag{D.1}\\
-1.4615 \cos (2 \Gamma)-4.089 \sin (2 \Gamma)] \\
\Gamma=360^{\circ} \frac{(n-1)}{365} \tag{D.2}
\end{gather*}
$$

The formulation given in Equations D. 1 and D. 2 is based on that given by Spencer (1971), and it appears in the above version in Chapter 14 of the ASHRAE Hand-book-Fundamentals (2013). For the examples used in this book, we use a slightly more convenient formulation given by Duffie and Beckman (1980):

$$
\begin{equation*}
\mathrm{ET}=9.87 \sin (2 B)-7.53 \cos (B)-1.5 \sin B \tag{D.3}
\end{equation*}
$$

where

$$
\begin{equation*}
B=360^{\circ} \frac{(n-81)}{364} \tag{D.4}
\end{equation*}
$$

The AST in hours is related to the LST, ET in minutes, the local standard meridian (LSM) in degrees, and the local longitude (LON) in degrees as follows:

$$
\begin{equation*}
\mathrm{AST}=\mathrm{LST}+\mathrm{ET} / 60+(\mathrm{LSM}-\mathrm{LON}) / 15 \tag{D.5}
\end{equation*}
$$

With the AST known, the computation of the angles shown in Figure D. 1 can proceed.

The hour angle $H$, in degrees, is calculated from the AST as follows:

$$
\begin{equation*}
H=15(\mathrm{AST}-12) \tag{D.6}
\end{equation*}
$$

The earth's pole is not orthogonal to the plane formed by the earth's orbit around the sun; it is tilted at an angle of $23.45^{\circ}$. As the earth rotates around the sun, the declination angle (that is, the angle between the earth's pole and a vector from the earth to the sun) varies. The declination in degrees can be read from Table D. 1 for the twentyfirst day of each month, or it can be related to the day of the year $n$ by:

$$
\begin{align*}
\delta= & 0.3963723-22.9132745 \cos (\Gamma)+4.0254304 \sin (\Gamma)-0.387205 \cos (2 \Gamma)  \tag{D.7}\\
& +0.05196728 \sin (2 \Gamma)-0.1545267 \cos (3 \Gamma)+0.08479777 \sin (3 \Gamma)
\end{align*}
$$

where $\Gamma$ is as defined in Equation D.2. Chapter 14 of the ASHRAE Handbook-Fundamentals (2013) gives a simpler formulation (Cooper 1969):

$$
\begin{equation*}
\delta=23.45 \sin \left(360^{\circ} \frac{n+284}{365}\right) \tag{D.8}
\end{equation*}
$$

The solar altitude angle $\beta$ is related to the latitude angle $L$ of the location, the declination angle $\delta$, and the hour angle $H$ :

$$
\begin{equation*}
\sin \beta=\cos L \cos \delta \cos H+\sin L \sin \delta \tag{D.9}
\end{equation*}
$$

The solar azimuth angle measured from the south is given by

$$
\begin{equation*}
\cos \phi=\frac{\sin \beta \sin L-\sin \delta}{\cos \beta \cos L} \tag{D.10}
\end{equation*}
$$

Figure D. 1 Solar angles.
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 14, Figure 3).

When measured from the south, the solar azimuth angle is positive in the afternoon and negative in the morning. As this formulation is really derived for use in a northern-hemisphere application, a more general expression, giving solar azimuth angle in degrees clockwise from north, may be desirable:

$$
\begin{equation*}
\cos \phi=\frac{\sin \delta \cos L-\cos \delta \sin L \cos H}{\cos \beta} \tag{D.11}
\end{equation*}
$$

Note that, when using Equation D.10, the sign of the angle should be set after taking the inverse cosine, depending on whether it is before or after noon. On the other hand, when using Equation D.11, the inverse cosine function (regardless of the programming environment) does not distinguish between, for example, in the northern hemisphere, $\cos (\phi)=0.9$, meaning $154.16^{\circ}$ in the morning and $\cos (\phi)=0.9$, meaning $205.84^{\circ}$ in the afternoon.

Likewise, in the southern hemisphere, the solar azimuth angle is positive in the morning, zero at noon, and negative in the afternoon. Again, the inverse cosine function cannot differentiate between $45^{\circ}$ (morning) and $315^{\circ}$ (afternoon). A general correction can be applied by checking to see if the hour angle $H$ is greater than zero. If so, then let

$$
\begin{equation*}
\phi=2 \pi-\phi \text { (in radians) or } \phi=360^{\circ}-\phi \tag{D.12}
\end{equation*}
$$

The surface azimuth angle $\psi$ is defined as the angle between OS and OP in Figure D.1, with surfaces facing west of south having positive surface azimuth angles and surfaces facing east of south having negative surface azimuth angles. When the solar azimuth is defined in terms of the angle clockwise from due north, the surface azimuth should also be defined in terms of the angle clockwise from due north. As long as the convention is the same for both the solar azimuth and the surface azimuth, the difference between the two, $\gamma$, is given by

$$
\begin{equation*}
\gamma=\phi-\psi \tag{D.13}
\end{equation*}
$$

## Load Calculation Applications Manual (I-P), Second Edition

If the solar-surface azimuth angle is greater than 90 or less than -90 , the surface is shaded. The angle of incidence $\theta$, the angle between the sun's rays and the normal to the surface, is given by

$$
\begin{equation*}
\cos \theta=\cos \beta \cos \gamma \sin \Sigma+\sin \beta \cos \Sigma \tag{D.14}
\end{equation*}
$$

where $\Sigma$ is the tilt angle of the surface, $\Sigma=0^{\circ}$ corresponds to a horizontal surface, and $\Sigma=90^{\circ}$ corresponds to a vertical surface.

## D. 2 ASHRAE Clear-Sky Model

The ASHRAE clear-sky model (Thevenard and Gueymard 2013) is used to estimate beam and diffuse irradiation incident on any surface for clear-sky conditions. Note that the term "clear sky" represents a theoretical maximum of total solar irradiation. In most locations, this means an absence of clouds, but in some locales, the sky may still be hazy. Once the solar angles have been determined, the next step is to determine the solar irradiation outside the earth's atmosphere; the extraterrestrial solar irradiation varies over the year because of the earth's elliptical orbit. The extraterrestrial solar irradiation is given by

$$
\begin{equation*}
E_{o}=E_{S C}\left\{1+0.033 \cos \left[360^{\circ} \frac{(n-3)}{365}\right]\right\} \tag{D.15}
\end{equation*}
$$

where $E_{S C}$ is the extraterrestrial solar constant, $433.3 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$.
The earth's atmosphere attenuates the extraterrestrial solar irradiation. This attenuation depends on the path length through the atmosphere and the turbidity of the atmosphere. Thevenard and Gueymard (2010) developed a widely applicable model with data available for the entire set of ASHRAE design weather data. Use of the model is summarized here; for a more detailed description, see Gueymard and Thevenard (2009) and Chapter 14 of the ASHRAE Handbook-Fundamentals (2013).

First, the relative air mass $m$ is computed depending on the solar altitude angle $\beta$ :

$$
\begin{equation*}
m=1 /\left\lfloor\sin \beta+0.50572(6.07995+\beta)^{-1.6364}\right\rfloor \tag{D.16}
\end{equation*}
$$

Then the beam optical depth $\tau_{b}$ and diffuse optical depth $\tau_{d}$ are determined for the specific location and month of interest from the design weather data in the accompaning online files. Table 4.1 and Tables 4.4 through 4.8 contain these data for sample locations. With these values, the air mass exponents $a b$ and $a d$ may be computed:

$$
\begin{align*}
& \quad a b=1.454-0.406 \tau_{b}-0.268 \tau_{d}+0.021 \tau_{b} \tau_{d}  \tag{D.17}\\
& a d=0.507+0.205 \tau_{b}-0.080 \tau_{d}-0.190 \tau_{b} \tau_{d} \tag{D.18}
\end{align*}
$$

Once the optical depths and air mass exponents have been determined, the beam normal irradiance (solar radiation flux perpendicular to the rays from the sun) is calculated:

$$
\begin{equation*}
E_{b}=E_{o} e^{-\tau_{b} m^{a b}} \tag{D.19}
\end{equation*}
$$

The diffuse horizontal irradiance is calculated as follows:

$$
\begin{equation*}
E_{d}=E_{o} e^{-\tau_{d} m^{a d}} \tag{D.20}
\end{equation*}
$$

## D. 3 Solar Irradiation on Surfaces

The shortwave-beam (direct) solar radiation $E_{t, b}\left(\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}\right)$ incident on a surface is given by

$$
\begin{equation*}
E_{t, b}=E_{b} \cdot \cos \theta \tag{D.21}
\end{equation*}
$$

Diffuse irradiation incident on a surface from the sky is calculated in two different ways, depending on the tilt of the surface. The diffuse solar irradiation on a vertical surface is given by the following:

$$
\begin{equation*}
E_{t, b}=Y \cdot E_{d} \tag{D.22}
\end{equation*}
$$

$$
\begin{array}{rlrl}
Y & =0.45 & \text { for } \cos \theta<-0.20  \tag{D.23}\\
Y & =0.55+0.437 \cos \theta+0.313 \cos ^{2} \theta & & \text { for } \cos \theta \geq-0.20
\end{array}
$$

where $Y$ is the ratio of diffuse solar radiation on vertical surfaces to a horizontal surface. For nonvertical surfaces, the diffuse irradiation is given by the following:

$$
\begin{gather*}
E_{t, d}=E_{d}(Y \sin \Sigma+\cos \Sigma) \text { if } \Sigma \leq 90^{\circ}  \tag{D.24}\\
E_{t, d}=E_{d} Y \sin \Sigma \text { if } \Sigma>90^{\circ} \tag{D.25}
\end{gather*}
$$

where $\Sigma$ is the surface tilt angle.
The ground-reflected diffuse solar irradiation is given by

$$
\begin{equation*}
E_{t, r}=\left(E_{b} \sin \beta+E_{d}\right) \rho_{g}\left(\frac{1-\cos \Sigma}{2}\right) \tag{D.26}
\end{equation*}
$$

where $\rho_{g}$ is the ground reflectivity (which may be estimated from Table D.2). Finally, for an unshaded surface, the total solar irradiation is

$$
\begin{equation*}
E_{t}=E_{t, b}+E_{t, d}+E_{t, r} \tag{D.27}
\end{equation*}
$$

## D. 4 Exterior Shading of Fenestration

Exterior shading of windows by overhangs or other devices can have a significant effect on solar heat gains. In many cases, the geometry can be represented as shown in Figure D.3, with the horizontal and vertical dimensions of the shading device sufficiently large so that the shadow has only horizontal and vertical components on the window. For these cases, the analysis given below is sufficient. In other cases, a procedure such as that described by Walton (1979) might be used.

Prior to calculating the shadow dimensions, the solar altitude angle $\beta$ and the surface solar azimuth angle $\gamma$ will have already been calculated with Equations D. 9 and D.13. As shown in Figure D.2, the profile angle $\Omega$ for the horizontal projection is given by

$$
\begin{equation*}
\tan \Omega=\frac{\tan (\beta)}{\cos (\gamma)} \tag{D.28}
\end{equation*}
$$

The shadow width $S_{W}$ and the shadow height $S_{H}$ of the horizontal overhang are given by the following

$$
\begin{equation*}
S_{W}=P_{V} \cdot|\tan \gamma| \tag{D.29}
\end{equation*}
$$

Table D. 2 Solar Reflectances of Foreground Surfaces
(Source: ASHRAE Handbook-Fundamentals [2013], Chapter 14, Table 5)

| Foreground Surface | Reflectance |
| :--- | :---: |
| Water (near normal incidences) | 0.07 |
| Coniferous forest (winter) | 0.07 |
| Asphalt, new | 0.05 |
| $\quad$ weathered | 0.10 |
| Bituminous and gravel roof | 0.13 |
| Dry bare ground | 0.2 |
| Weathered concrete | 0.2 to 0.3 |
| Green grass | 0.26 |
| Dry grassland | 0.2 to 0.3 |
| Desert sand | 0.4 |
| Light building surfaces | 0.6 |
| Snow-covered surfaces: |  |
| Typical city center | 0.2 |
| Typical urban site | 0.4 |
| Typical rural site | 0.5 |
| Isolated rural site | 0.7 |

Source: Adapted from Thevenard and Haddad (2006).

Figure D. 2 Shading for vertical and horizontal projections.
(Source: ASHRAE Handbook—Fundamentals [2013], Chapter 15, Figure 16).

$$
\begin{equation*}
S_{H}=P_{H} \cdot \tan \Omega \tag{D.30}
\end{equation*}
$$

where $P_{V}$ and $P_{H}$ are the horizontal and vertical projection distances shown in Figure D.2.
The fenestration sunlit and shaded areas can then be calculated:

$$
\begin{equation*}
A_{S L}=\left[W-\left(S_{W}-R_{W}\right)\right] \cdot\left[H-\left(S_{H}-R_{H}\right)\right] \tag{D.31}
\end{equation*}
$$

$$
\begin{equation*}
A_{S H}=A-A_{S L} \tag{D.32}
\end{equation*}
$$

where $A$ is the total fenestration surface area and $R_{W}$ and $R_{H}$ are dimensions shown in Figure D.3.

The sunlit window area fraction $A_{S L, F}$ is calculated from the ratio of the sunlit area to the total window area as follows:

$$
\begin{equation*}
A_{S H, F}=A_{S L} / A \tag{D.33}
\end{equation*}
$$

## D. 5 Sol-Air Temperature Calculation

Sol-air temperature is the outdoor air temperature that, in the absence of all radiation heat transfer, gives the same rate of heat flowing into the surface as would the combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with outdoor air. The solair temperature $T_{S A}$ is given by the following:

$$
\begin{equation*}
T_{S A}=T_{o}+\frac{\alpha E_{t}}{h_{o}}-\frac{\varepsilon \Delta R}{h_{o}} \tag{D.34}
\end{equation*}
$$

where
$T_{\mathrm{o}}=$ outdoor air temperature, ${ }^{\circ} \mathrm{F}$
$\alpha=$ surface solar absorptance
$h_{\mathrm{o}}=$ combined outside surface conductance, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$E_{\mathrm{t}}=$ total solar irradiation on the surface, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$

Figure D. 3 Solar input data.

## Load Calculation Applications Manual (I-P), Second Edition

$\Delta R=$ difference between the radiation emitted by a blackbody at the outdoor air temperature and the actual thermal radiation incident on the surface from the sky and surroundings, Btu/h $\cdot \mathrm{ft}^{2}$
$\varepsilon \quad=$ surface emissivity
The total solar irradiation is computed from the beam, diffuse, and reflected components calculated using Equation D.27.

The third term of Equation D. 34 is effectively a correction for the fact that the sky and surroundings are not at the local air temperature. For horizontal surfaces that view the sky, this correction is taken as $7^{\circ} \mathrm{F}$. For vertical surfaces, where the view to the sky and the higher temperature surroundings may be approximately equal, the correction is usually taken to be $0^{\circ} \mathrm{F}$.

The value of the parameter $\alpha / h_{o}$ depends on surface color. A value of 0.15 is appropriate for a light-colored surface with a solar absorptance of 0.6 and a summer surface conductance of 4 , whereas 0.23 represents the usual maximum value for this parameter (i.e., for a dark-colored surface with a solar absorptance of 0.9 and summer surface conductance of 4). Values for the combined conductance $h_{o}$, which depends on wind speed, are given in Table 3.4 in Chapter 3.

## D. 6 Spreadsheet Implementation

This section describes a spreadsheet implementation of the solar irradiation and sol-air temperature calculations for the eight cardinal directions and a horizontal surface. Solar irradiation and sol-air temperatures are calculated for the 21st day of each month under clear-sky and design cooling conditions.

The spreadsheet $D-1$ solar.xls, included in the supporting files accompanying this manual (online at www.ashrae.org/lcam), initially opens with a screen (shown in Figure D.3) showing a summary of preexisting input data. Clicking on the button labeled Solar Intensity \& Sol-Air Temperature will bring up the input dialog box shown in Figure D.4.

There are five categories of inputs as shown in the user form in Figure D.4.
All input parameters have default values provided, though they may be completely irrelevant to the user's situation. The user may select either SI or I-P units. Local time or solar time, which controls the basis on which solar irradiation and solair temperature are tabulated, may also be chosen. Beyond that, almost all the rest of the parameters may be set automatically by selecting one of the climate/design day combinations. For other locations, all parameters may be specified individually by typing their values in the appropriate field. The parameters are summarized in Table D.3.

The solar irradiation and sol-air temperature calculations use the equations given in this chapter. The input parameters are described in Table D.3. The default values have the units of the default unit system, which is I-P.

Once all of the parameters are set, clicking on $O K$ will create a new worksheet, which will hold a series of tables of solar irradiation values and sol-air temperatures. Choosing $0.4 \%$ conditions for Gage, Oklahoma, for example, will give tables for which Figure D. 5 is a small excerpt.

How does this work? While a complete explanation is beyond the scope of this manual, interested readers may explore the Visual Basic for Applications (VBA) source code. (In Excel 2003, this is done from the Tools menu by choosing Macro, then Visual Basic Editor.) In Excel 2013, this is done by choosing the Developer tab,

## Solar Parameters

Table D. 3 Input Parameter Descriptions

| Input Parameters | Default Values | Note |
| :---: | :---: | :---: |
| Location | Atlanta, Georgia | A combo-box allows selecting the location. This sets most of the other parameters below. |
| Design Condition | 5\% | A combo-box allows the user to select the desired monthly design conditions $(0.4 \%, 2 \%$, $5 \%$ or $10 \%$ ) |
| Latitude | 33.64 | When a location is selected, the corresponding latitude is retrieved. |
| Longitude | 84.43 | When a location is selected, the corresponding longitude is retrieved. |
| Time zone | 5.0 | When a location is selected, the corresponding time zone is retrieved. |
| Facing direction | 0, 45, 90, ... 315 | The eight cardinal directions. Users can edit the facing directions to other values. The angles are measured clockwise from true north. |
| Tilt angle | 90 | For all walls except the roof. By default the roof is considered horizontal. |
| Month | All | The 12 months of the year. Users can specify the months by using integer values 1,2 , or $3, \ldots, 12$. A single month can also be specified. |
| Day | 21 | Users can specify the day of the month. |
| Daylight savings time | Yes | Enforces daylight savings time. |
| Taub | Atlanta, Georgia | $\mathrm{Tau}_{b}$ is retrieved from the ASHRAE design day database sheet when a location is selected by the user. |
| Taud | Atlanta, Georgia | $\mathrm{Tau}_{d}$ is retrieved from the ASHRAE design day database sheet when a location is selected by the user |
| Ground reflectance | 0.2 | Table D.2. |
| Design temperature | Atlanta, Georgia | The peak design temperature is retrieved from the ASHRAE design day database sheet (featured on the CD that accompanies the ASHRAE Handbook-Fundamentals (2013) (WDATA_SI or WDATA_IP) when a location is selected by the user. |
| Daily range | Atlanta, Georgia | The design day daily range is retrieved from the ASHRAE design day database sheet (featured on the CD that accompanies the ASHRAE Handbook-Fundamentals (2013) (WDATA_SI or WDATA_IP) when a location is selected by the user. |
| Absorptance | 0.9 | Outside surface short-wavelength absorptance. |
| Conductance | 4 | Outside conductance. |

Both cooling load calculation procedures described in this manual use onedimensional transient conduction analysis procedures with precomputed conduction transfer functions (for the heat balance method [HBM]) or conduction time series factors (for the radiant time series method [RTSM]). In both cases, the first step is to describe the wall, roof, or floor as a series of one-dimensional homogeneous layers. For cases with thermal bridges, a method to determine an equivalent wall made up of one-dimensional homogeneous layers is needed. Karambakkam et al. (2005) proposed an approximate one-dimensional procedure for dynamic modeling of thermal bridges, and validation of the model was reported by Nigusse (2007).

## E. 1 Equivalent Homogeneous Layer Model

The equivalent homogeneous layer (EHL) model (Karambakkam et al. 2005) is suitable for walls with a single composite layer (e.g., steel studs and insulation). The model determines the thermal characteristics of the homogeneous layer such that both the overall wall resistance and the composite layer's thermal mass are maintained. The first step, then, is to determine the total thermal resistance of the actual construction, as discussed in the next section.

The EHL has the following properties:

- Thickness is the same as the thickness of the composite layer.
- Conductivity is determined from the resistance of the EHL required to maintain the overall thermal resistance of the wall and the thickness of the composite layer.
- Density is the volume-weighted average of the densities of the composite layer materials.
- Specific heat is determined from a mass-weighted average of the specific heats of the composite layer materials.

The accuracy of the EHL model in duplicating the actual construction depends on the accuracy of the steady-state thermal resistance or R-value. Nigusse (2007) showed that the EHL model predicted peak conduction heat gain within $\pm 3 \%$ of experimental results for seven walls with experimental measurements when the experimentally measured R-value was used to determine the EHL properties. However, methods for estimating steady-state R-values, discussed in the next section, introduce additional error. Using the recommended methods for estimating R-values, the error of the EHL model rose to $\pm 8 \%$ of the experimentally measured peak conduction heat gain for six of the seven walls. The seventh wall had an error in predicted peak conduction heat gain of $19 \%$, due to an error of more than $11 \%$ in the ASHRAE Handbook-Fundamentals (2005) method for estimating the R -value.

## E. 2 Steady-State R-Value

The ASHRAE Handbook-Fundamentals (2013) provides a range of procedures for estimating R-values and U-factors for walls with thermal bridge elements: the isothermal planes method, the parallel path method, the zone method, and the modified zone method. The reader is referred to pages 27.3-27.7 of the ASHRAE Handbook-Fundamentals (2013). One additional method that should be considered for walls with steel studs was recently published by Gorgolewski (2007) and is described briefly as follows.

## Load Calculation Applications Manual (I-P), Second Edition

Gorgolewski (2007) gives a semi-empirical correlation for computing the steady-state R -value of light frame steel stud walls. This procedure uses a weighted average of the isothermal plane and parallel-path method R -values. (The two methods bound the possible range of R -values.) The weighting parameter $p$ is calculated from a semi-empirical correlation that depends on the geometry of the steel frame and R-values determined by the isothermal and parallel-path methods. For I-P units,

$$
\begin{equation*}
p=0.8\left(R_{\min } / R_{\max }\right)+0.44-0.1(w / 1.5)-0.2(24 / s)-0.04(d / 4) \tag{E.1}
\end{equation*}
$$

where
$R_{\text {min }}=$ is the R-value of the steel stud construction calculated with the isothermal plane method, $\mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}\left(\mathrm{m}^{2} \cdot \mathrm{~K} / \mathrm{W}\right)$
$R_{\text {max }}=$ is the R -value of the steel stud construction calculated with the parallel path method, $\mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}\left(\mathrm{m}^{2} \cdot \mathrm{~K} / \mathrm{W}\right)$
$w \quad=$ steel stud flange width, in. (mm)
$s \quad=$ the studs center-to-center spacing, in. (mm)
$d \quad=$ depth of the stud, in. (mm)
With the weighting parameter determined, the R -value is then given by

$$
\begin{equation*}
R_{T}=p R_{\max }+(1-p) R_{\min } \tag{E.2}
\end{equation*}
$$

Once the overall wall R-value has been determined, the EHL properties may be determined, as described next.

## E. 3 EHL Step-by-Step Procedure

The EHL model (Karambakkam et al. 2005) relies on accurate knowledge of the air-to-air or surface-to-surface R-value and the geometry of the actual construction. The step-by-step procedure for calculating the EHL model wall for cases with a single composite layer is described as follows:

1. Determine the overall resistance of the actual construction based on one of the methods listed in the previous section. For use with the RTSM, the overall resistance should include the surface resistances on both sides of the construction. For use with the HBM, where variable convection and radiation coefficients are a possibility, an estimate of the surface resistances under peak heat gain conditions should be made.
2. Compute the effective equivalent resistance of the homogenous layer based on the actual overall resistance determined in the previous step. The EHL resistance is the difference between the actual thermal resistance and the sum of the homogeneous layer resistances in the actual construction and is given by the following:

$$
\begin{equation*}
R_{\text {Hom }}=R_{T}-\sum_{i=1}^{N} R_{i} \tag{E.3}
\end{equation*}
$$

where
$R_{T}=$ the steady-state, overall air-to-air thermal resistance of the construction, $\mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$
$R_{i}=$ the thermal resistance of the $i$ th homogeneous layer in the construction, $\mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$
$R_{\text {Hom }}=$ the thermal resistance of the equivalent homogeneous layer, $\mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$
$N=$ the number of homogeneous layers in the actual construction
Note that the summation does not include the composite layer.

3. Thermal conductivity of the EHL is obtained by dividing the thickness of the EHL with the resistance of the EHL. The thickness of the EHL is equal to the thickness of the composite layer or the total thickness minus the thickness of the homogenous layers:

$$
\begin{equation*}
X_{H o m}=X_{T o t}-\sum_{i=1}^{N} X_{S l, i} \tag{E.4}
\end{equation*}
$$

The conductivity is then the thickness divided by the resistance:

$$
\begin{equation*}
k_{\text {Hom }}=\frac{X_{\text {Hom }}}{R_{\text {Hom }}} \tag{E.5}
\end{equation*}
$$

where
$X_{\text {Tot }}=$ the overall thickness of the actual construction, in.
$X_{H o m}=$ the thickness of the equivalent homogeneous layer, in.
$X_{S l, i}=$ the thickness of the $i$ th single homogeneous layer in the construction, in.
$k_{\text {Hom }}=$ the thermal conductivity of the EHL, Btu•in. $/ \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
4. Density of the EHL is determined from densities of the components of the composite layers and the corresponding volume fractions. The product sum of the volume fraction and densities of the components in the composite layer yields the EHL density and is given by the following:

$$
\begin{equation*}
\rho_{\text {Hom }}=\sum_{i=1}^{M} y_{i} \rho_{i} \tag{E.6}
\end{equation*}
$$

where
$y_{i} \quad=$ the volume fraction of $i$ th component in the composite layer(s)
$\rho_{i} \quad=$ the density of the $i$ th component in the composite layer(s), $\mathrm{lb}_{\mathrm{m}} / \mathrm{ft}^{3}$
$\rho_{\text {Hom }}=$ the density of the EHL, $\mathrm{lb}_{\mathrm{m}} / \mathrm{ft}^{3}$
The constituents' volume fraction in the composite layer is determined from the geometry of the composite layer.
5. The specific heat of the homogeneous layer is determined from the product sum of the specific heat, densities, and volume fractions of the constituents of the composite layers:

$$
\begin{equation*}
C_{p, \text { Hom }}=\sum_{i=1}^{M} y_{i} \rho_{i} C_{p i} / \rho_{H o m} \tag{E.7}
\end{equation*}
$$

where
$C_{p i}=$ specific heat of the $i$ th component in the composite layer(s), $\mathrm{Btu} / \mathrm{lb}_{\mathrm{m}} \cdot{ }^{\circ} \mathrm{F}$
$C_{p, \text { Hom }}=$ specific heat of the EHL, $\mathrm{Btu} / \mathrm{lb}_{\mathrm{m}} \cdot{ }^{\circ} \mathrm{F}$
Once the thickness and thermophysical properties of the EHL have been determined, the EHL model wall can be input and analyzed as if it were made up of homogeneous layers.

The EHL wall model is demonstrated using a generic-type steel stud wall as shown in Figure E. 1 with 16 in. center-to-center stud spacing and 3.5 in. deep studs with 1.5 in . flange width and 0.059 in . thickness. The thermophysical properties of the construction layer materials are given in Table E.1. The problem to be solved is to find the properties of the EHL.

Solution: Step 1: Calculation of the overall steady-state resistance. The Gorgolewski (2007) procedure is used to estimate the steady-state, surface-tosurface, overall R-value of the steel stud wall. This procedure requires calculation of the overall resistances using the isothermal plane method and parallel path method.

The isothermal plane method combines in parallel the resistances of the elements of the composite layer and then sums the resistances of each layer in the construction. The resistance of the composite layer is given by the following:

$$
\begin{equation*}
R_{C L}=\frac{1}{\frac{A_{f, \text { metal }}}{R_{\text {metal }}}+\frac{A_{f, \text { insulation }}}{R_{\text {insulation }}}}=2.451 \mathrm{ft}^{2} \cdot \mathrm{~h} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu} \tag{E.8}
\end{equation*}
$$

where
$A_{f, \text { metal }}=$ area fraction of the metal stud
$A_{f, \text { insulation }}=$ area fraction of the insulation
$R_{\text {metal }} \quad=$ resistance of the metal stud
$R_{\text {insulation }}=$ resistance of the insulation
The individual layer resistances and the combined resistance of the composite layer are given in Table E.2; the total resistance of the construction using the isothermal plane method is given in the last line of the table-this is the $R_{\text {min }}$ value.

The parallel path method computes the total resistances (see Table E.3) for heat transfer through the insulation path and metal stud path separately and then adds them together in parallel:

$$
\begin{equation*}
R_{\max }=\frac{1}{\frac{A_{f, \text { metal }}}{R_{m p}}+\frac{A_{f, \text { insulation }}}{R_{i p}}}=23.428 \mathrm{ft}^{2} \cdot \mathrm{~h} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu} \tag{E.9}
\end{equation*}
$$

With $R_{\max }$ and $R_{\min }$ computed, Equation E. 1 can be used to determine the weighting parameter, $p$ :
$p=0.8(13.016 / 23.428)+0.44-0.1(1.5 / 1.5)-0.2(24 / 16)-0.04(3.5 / 4)=0.449$

## Load Calculation Applications Manual (I-P), Second Edition

Then, Equation E. 2 can be used to find the total resistance:

$$
R_{T}=0.449 \cdot 23.428+(1-0.449) 13.016=17.696 \mathrm{ft}^{2} \cdot \mathrm{~h}^{\circ} \mathrm{F} / \mathrm{Btu}
$$

Step 2: Calculation of the equivalent layer thermal resistance. The EHL resistance is given by Equation E.3:

$$
\begin{gather*}
R_{\text {Hom }}=R_{T}-\sum_{i=1}^{N} R_{i}  \tag{E.3}\\
R_{\text {Hom }}=17.696-10.564=7.132 \mathrm{ft}^{2} \cdot \mathrm{~h} \cdot{ }^{\circ} \mathrm{F} / \mathrm{Btu}
\end{gather*}
$$

Step 3: Calculation of the EHL thermal conductivity. The thermal conductivity of the equivalent layer is calculated using Equation E.5:

$$
k_{\text {Hom }}=\frac{3.5}{7.132}=0.49 \mathrm{Btu} \cdot \mathrm{in} . /^{\circ} \mathrm{F} \cdot \mathrm{ft}^{2} \cdot \mathrm{~h}
$$

Step 4: Calculation of the equivalent layer (composite layer) density. The volume fraction of the metal in the composite layer is determined from the metal stud parameters given in the problem description as follows:

$$
y_{\text {steel }}=\frac{(3.5+2 \cdot 1.5) \cdot 0.059}{3.5 \cdot 16}=0.007
$$

Similarly, for the insulation section in a two-component composite layer, the volume fraction is given by

$$
y_{\text {insulation }}=1-\frac{(3.5+2 \cdot 1.5) \cdot 0.059}{3.5 \cdot 16}=0.993
$$

The density of the equivalent layer is given by Equation E.6:

$$
\rho_{H}=474.5 \cdot 0.007+0.905 \cdot 0.993=4.15 \mathrm{lb}_{\mathrm{m}} / \mathrm{ft}^{3}
$$

Step 5: Calculation of the equivalent layer (composite layer) specific heat. Using the volume fraction of the steel and insulation determined in step 4, the specific heat of the composite layer is determined as follows:

$$
c_{p}=\frac{(474.5 \cdot 0.120 \cdot 0.007+0.905 \cdot 0.170 \cdot 0.993)}{4.15}=0.13 \quad \mathrm{Btu} / \mathrm{lb}_{\mathrm{m}} \cdot{ }^{\circ} \mathrm{F}
$$

The thermophysical properties of the wall layers are summarized in Table E.4, with the EHL shown in bold.

The astute reader may note that adding all of the resistances gives a value of 17.707, which is slightly higher than the resistance used to compute the EHL properties (17.696). This results from only carrying the EHL conductivity to two decimal places (i.e., 0.49 instead of 0.4908 ). Using 0.4908 gives an EHL resistance of 17.696.

Finally, once the EHL properties have been computed, conduction transfer functions or conduction time factor series can be readily computed using the layer-bylayer description.

## Appendix F Treatment of Uncontrolled Spaces

This appendix briefly describes treatment of unconditioned and/or uncontrolled spaces such as return air plenums, attics, crawlspaces, and attached garages. Whether for nonresidential buildings or residential buildings, the physics are the same. In either case, an estimate of the space air temperatures in the uncontrolled spaces is often needed to determine the heat flow between the conditioned space(s) and unconditioned space(s). There are several possible approaches:

- For heating load calculations, a simple conservative estimate that uninsulated, uncontrolled spaces are at the outdoor temperature may be sufficient.
- Using a steady-state heat balance, estimate the temperature at each desired condition (i.e., the heating design condition and each hour of the day for cooling load calculations). In some cases, it might be sufficient to estimate a single temperature for cooling load calculations; however, the temperature of an uncontrolled space will generally change throughout the day. This approach has the advantage of being feasible for manual or spreadsheet calculation. For cooling load calculations, it has the disadvantage of ignoring heat storage in the building fabric.
- Using a transient heat balance (i.e., the heat balance method [HBM]), compute the temperature of the uncontrolled space at each hour of the day for cooling load calculations. This approach can also be used for heating load calculations, but with the typical assumptions used in heating load calculations, it is effectively a steady-state calculation.

In considering which approach to use, three factors should be considered:

1. The importance of the heat transfer between the conditioned space and the uncontrolled space. Specifically, if the conductance between the two spaces is relatively small (i.e., if the surface dividing the two spaces is well insulated) and if the likely heat transfer between the two spaces is small relative to other heat gains, the simpler steady-state heat balance is probably appropriate.
2. The construction of the building, specifically the thermal mass, may be important in considering whether a transient heat balance is needed. If there is significant thermal mass between the outside and the uncontrolled space, a steady-state heat balance may be inadequate.
3. The likely space air temperature variation in the uncontrolled space over a cooling load calculation day may be important. If it is small, then the steady-state heat balance may be appropriate, regardless of other factors.

For example, consider an attic space in a conventionally constructed wood frame house. The space air temperature variation is large under most cooling load conditions, but the thermal mass of the surface between the outside and the uncontrolled space (composite shingles and plywood deck) is relatively small, so an hourly steady-state heat balance would be acceptable. Furthermore, if the attic floor is well insulated, the heat transfer rate will be relatively small, again suggesting that a steady-state heat balance will be adequate.

As another example, consider the space between an uninsulated 4 in. thick concrete roof deck and a suspended acoustical tile ceiling. Although such a construction could not be recommended from an energy perspective, it does serve as a good example of the need for a transient heat balance. In this case, the conductance between the unconditioned space and the conditioned space is high. There is significant thermal mass in the surface separat-
ing the outside and the uncontrolled space (the 4 in. thick concrete roof deck), and a high space air temperature variation would be expected. So, a transient heat balance would be recommended in this case, unless the distance from the roof deck to the acoustic tile was small relative to the length and width of the roof. If the distance is small, it would be much simpler to treat the roof deck, air space, and acoustical tile as the layers of the exterior roof construction. On the other hand, if the distance is not small relative to the length and width of the roof deck, the side walls of the space might make an important contribution to the temperature, and, therefore, a transient heat balance would be recommended.

If a transient heat balance is necessary, the engineer should use a computer program that implements the HBM and that allows space air temperatures computed for uncontrolled spaces to be used as other side boundary conditions for conditioned spaces. For the majority of cases, a steady-state heat balance is adequate. An example follows.

## Example F. 1 Unheated Mechanical Room

A small mechanical room in a building is unheated. A plan view of the building is shown in Figure F. 1 with the mechanical room labeled; the rest of the building is conditioned. Additional information about the building is given below.

The U-factors and areas are summarized in Table F.1. Additional building details are as follows:

- Under design heating conditions, the outdoor air is at $10^{\circ} \mathrm{F}$ and the conditioned space is at $70^{\circ} \mathrm{F}$.
- The building is 12 ft high and has a flat roof.
- The steel building is built on a concrete slab, which is uninsulated. The perimeter heat loss coefficient $F_{p}$ is taken from Table 10.3 as $1.20 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}{ }^{\circ} \mathrm{F}$.
- Infiltration in the uncontrolled mechanical room may be assumed to be 60 cfm .
- Atmospheric pressure is 14.7 psia ; specific volume of air at $10^{\circ} \mathrm{F}$ is $11.85 \mathrm{ft}^{3} / \mathrm{lb}_{\mathrm{m}} ; c_{p}$ is $0.24 \mathrm{Btu} / \mathrm{lb}_{\mathrm{m}}{ }^{\circ}{ }^{\circ}$.

Mechanical room

Figure F. 1 Plan view of building with uncontrolled mechanical room.

## Appendix F: Treatment of Uncontrolled Spaces

Under design heating conditions, find the temperature in the mechanical room and the heat loss from the conditioned space to the mechanical room.

Solution: A steady-state heat balance is performed by balancing all of the heat flows into and out of the mechanical room. These include conduction heat transfer from the conditioned space into the mechanical room, conduction heat transfer from the mechanical room to the outside, and infiltration heat loss.

Conduction Heat Transfer from the Conditioned Space into the Mechanical Room. As stated in Chapter 10, for above-grade surfaces, conduction heat losses are formulated in terms of a heating factor HF and the surface area $A$ (Equations 10.1 and 10.2):

$$
\begin{array}{r}
q=A \cdot H F \\
H F=U \Delta t
\end{array}
$$

where $H F$ is the heating load factor in $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2}$.
Combining the two equations,

$$
\begin{equation*}
q=U A \cdot \Delta t \tag{F.1}
\end{equation*}
$$

For the walls between the conditioned space and the mechanical room, the heat transfer from the conditioned space to the mechanical room is

$$
\begin{equation*}
q_{c s-m r, w a l l s}=U A_{i w} \cdot\left(t_{i w}-t_{b}\right) \tag{F.2}
\end{equation*}
$$

where
$t_{\text {in }}=$ the inside air temperature, ${ }^{\circ} \mathrm{F}$
$t_{b}=$ the mechanical room air temperature, ${ }^{\circ} \mathrm{F}$
$U A_{i w}=$ the overall heat transfer coefficient for the interior walls, $\mathrm{Btu} / \mathrm{h} \cdot{ }^{\circ} \mathrm{F}$
In addition, there will be a similar expression for heat transfer through the doors:

$$
\begin{equation*}
q_{c s-m r, \text { doors }}=U A_{i d} \cdot\left(t_{i n}-t_{b}\right) \tag{F.3}
\end{equation*}
$$

where $U A_{i d}$ is the overall heat transfer coefficient for the interior doors in $\mathrm{Btu} / \mathrm{h} \cdot{ }^{\circ} \mathrm{F}$.
There will also be a small amount of heat transfer from the conditioned space to the mechanical room via the slab, but we will neglect that.

Table F. 1 U-Factors and Areas for Example F. 1

| Surface | $\boldsymbol{U}, \mathbf{B t u} / \mathbf{h} \cdot \mathrm{ft}^{\mathbf{2} \cdot{ }^{\circ} \mathbf{F}}$ | $\boldsymbol{A}, \mathrm{ft}^{\mathbf{2}}$ | $\boldsymbol{U A}, \mathbf{B t u} / \mathbf{h} \cdot{ }^{\circ} \mathbf{F}$ |
| :--- | :---: | :---: | :---: |
| Roof | 0.04 | 180 | 7.2 |
| Exterior wall | 0.07 | 138 | 9.7 |
| Exterior (man) doors <br> Wall between conditioned <br> space and mechanical room <br> Door between conditioned space <br> and mechanical room 0.60 | 42 | 25.2 |  |

Conduction Heat Transfer from the Mechanical Room to the Outside. Similarly, for the wall between the mechanical room and the outside, the heat transfer is

$$
\begin{equation*}
q_{m r-o, \text { wall }}=U A_{o w} \cdot\left(t_{b}-t_{o}\right) \tag{F.4}
\end{equation*}
$$

where $t_{o}$ is the outdoor air temperature in ${ }^{\circ} \mathrm{F}$.
Again, there will also be heat transfer through the doors, and there will be a similar expression for this:

$$
\begin{equation*}
q_{m r-o, \text { doors }}=U A_{o d} \cdot\left(t_{b}-t_{o}\right) \tag{F.5}
\end{equation*}
$$

where $U A_{o d}$ is the overall heat transfer coefficient for the exterior doors in $\mathrm{Btu} / \mathrm{h} \cdot{ }^{\circ} \mathrm{F}$.
Likewise, for heat transfer through the roof,

$$
\begin{equation*}
q_{m r-o, r o o f}=U A_{o r} \cdot\left(t_{b}-t_{o}\right) \tag{F.6}
\end{equation*}
$$

where $U A_{o r}$ is the overall heat transfer coefficient for the roof in $\mathrm{Btu} / \mathrm{h} \cdot{ }^{\circ} \mathrm{F}$.
The heat loss from the slab is given in Chapter 10 as the following (Equations 10.7 and 10.8):

$$
\begin{aligned}
& q=p \cdot H F \\
& H F=F_{p} \Delta t
\end{aligned}
$$

where
$q=$ heat loss through perimeter, Btu/h
$F_{p}=$ heat loss coefficient per foot of perimeter, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft} \cdot{ }^{\circ} \mathrm{F}$ (Table 10.3)
$p=$ perimeter (exposed edge) of floor, ft
Combining the two equations, the heat loss from the mechanical room to the outside via the slab is

$$
\begin{equation*}
q_{m r-o, s l a b}=p \cdot F_{p}\left(t_{b}-t_{o}\right) \tag{F.7}
\end{equation*}
$$

Infiltration Heat Loss. For sea-level conditions, the infiltration heat loss is given by Equation 9.1c, which adapted to our situation, is

$$
\begin{equation*}
q_{\text {infiltration }}=1.1(\mathrm{cfm})\left(t_{b}-t_{o}\right) \tag{F.8}
\end{equation*}
$$

Heat Balance with No Internal Heat Gains. Assuming for now that there are no internal heat gains from equipment, a steady-state heat balance on the mechanical room air can be expressed in words as "the heat transfer rate into the mechanical room is equal to the heat transfer rate out of the mechanical room." Or, as

$$
\begin{gather*}
q_{c s-m r, \text { walls }}+q_{c s-m r, \text { doors }}=q_{m r-o, \text { walls }}+q_{m r-o, \text { doors }}  \tag{F.9}\\
+q_{m r-o, \text { roof }}+q_{m r-o, \text { slab }}+q_{\text {infiltration }}
\end{gather*}
$$

Then, substitute Equations F.2-F. 8 into F. 9 and solve for $t_{b}$ :

$$
\begin{equation*}
t_{b}=\frac{U A_{i w} t_{i n}+U A_{i d} t_{i n}+U A_{o w} t_{o}+U A_{o d} t_{o}+U A_{o r} t_{o}+p F_{p} t_{o}+1.1(\mathrm{cfm}) t_{o}}{U A_{i w}+U A_{i d}+U A_{o w}+U A_{o d}+U A_{o r}+p F_{p}+1.1(\mathrm{cfm})} \tag{F.10}
\end{equation*}
$$

## Appendix F: Treatment of Uncontrolled Spaces

Substituting in numerical values,

$$
\begin{gathered}
t_{b}=\frac{35.8 \cdot 70+8.4 \cdot 70+9.7 \cdot 10+25.2 \cdot 10+7.2 \cdot 10+15 \cdot 1.2 \cdot 10+1.1 \cdot 60 \cdot 10}{35.8+8.4+9.7+25.2+7.2+15 \cdot 1.2+1.1 \cdot 60} \\
t_{b}=25.6^{\circ} \mathrm{F} .
\end{gathered}
$$

The heat loss from the conditioned space to the mechanical room is determined by summing the heat transfer rates expressed in Equations F. 2 and F.3:

$$
q=U A_{i w} \cdot\left(t_{i n}-t_{b}\right)+U A_{i d} \cdot\left(t_{i n}-t_{b}\right)=35.8 \cdot(70-25.6)+8.4 \cdot(70-25.6)
$$

$$
\begin{equation*}
q=1964 \mathrm{Btu} / \mathrm{h} \tag{F.11}
\end{equation*}
$$

## F. 1 Additional Heat Transfer Paths

Other types of spaces, such as return air plenums, may have heat gains from lighting or equipment, airflows from other spaces, etc. The general approach is as illustrated above, though additional terms may be introduced into Equations F. 9 and F.10. One such example can be found in Section 8.5 of Chapter 8.

## Appendix G

## Correction Factor for High-Conductance Surface Zones

T
he radiant time series method (RTSM) generally performs as desired for a simplified cooling load calculation procedure-it has a small but acceptable amount of overprediction of peak cooling loads compared to the heat balance method (HBM). However, as shown previously by Rees et al. (1998), for zones with a significant amount of single-pane glass, the RTSM can overpredict the peak cooling load by as much as $37 \%$. To a lesser degree, zones with significant amounts of double-pane glazing (Nigusse 2007) have overprediction as high as $14 \%$. In theory, this could also be the case for other high-conductance surfaces, such as tents.

Nigusse (2007) developed a correction for zones that can be applied to the RTSM. It has been tested for a very wide range of test zones and can be applied to all zones or only to zones where significant overprediction is expected. The correction factor takes the form of a dimensionless conductance that is computed from the zone geometry, inside combined conductance, and overall U-factor of the fenestration. In addition, a slightly different value of radiative fraction is recommended for window solar heat gain.

## G. 1 Computation of Dimensionless Conductance

The dimensionless loss conductance is derived by Nigusse (2007). In the simplest form, for a room with one window, the dimensionless loss conductance is given as the following:

$$
\begin{equation*}
U^{*}=\frac{U_{\text {window }}}{h_{i, \text { window }}} \cdot \frac{A_{\text {window }}}{A_{\text {room }}} \tag{G.1}
\end{equation*}
$$

where
$U_{\text {window }}=\mathrm{U}$-factor for the window, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$h_{i, \text { window }}=$ inside surface conductance for the window, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{F}$; a typical value for a vertical window is $1.46 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} .{ }^{\circ} \mathrm{Ffrom}$ Table 3.4
$A_{\text {window }}=$ window surface area, $\mathrm{ft}^{2}$
$A_{\text {room }}=$ total interior surface area of the room, including furniture, $\mathrm{ft}^{2}$
For a room with $M$ windows, the dimensionless heat loss conductance would be given by the following:

$$
\begin{equation*}
U^{*}=\left(\frac{1}{A_{\text {room }}} \sum_{j=1}^{M} \frac{U_{j} A_{j}}{h_{i, j}}\right) \tag{G.2}
\end{equation*}
$$

where
$U_{j} \quad=\mathrm{U}$-factor for the $j$ th window, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$
$h_{i, j} \quad=$ inside surface conductance for the $j$ th window, $\mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$ (see Table 3.4)
$A_{j} \quad=j$ th window surface area, $\mathrm{ft}^{2}$
$A_{\text {room }}=$ total interior surface area of the room including furniture, $\mathrm{ft}^{2}$
For windows with interior shades, the U-factor would include the resistance of the shade and the air gap. For zones with two exterior façades, the dimensionless loss conductance, depending on the glazing fraction, may range from 0.01 to 0.14 .

## G. 2 Splitting Heat Gains into Radiative and Convective Portions

In Chapter 7, Section 7.7 describes the procedure for splitting the heat gains into radiative and convective portions and Table 7.10 gives the recommended splits. When using the correction factor, the procedure is identical, except that the recommended radiative fraction for solar heat gain through fenestration without interior shading is 0.9 instead of 1.0 . Table G. 1 is an excerpt from Table 7.10 , showing the modified values of radiative and convective fraction.

## G. 3 Correction of the Radiant Time Factor Series

The heat loss is accounted for by correcting the first terms of the solar and nonsolar radiant time factor series (RTF series). The corrected terms, for solar and nonsolar radiant time factors, are given by the following:

$$
\begin{align*}
& r_{s, 0, c}=\left(r_{s, 0}-U^{*}\right)  \tag{G.3}\\
& r_{n s, 0, c}=\left(r_{n s, 0}-U^{*}\right) \tag{G.4}
\end{align*}
$$

where
$U^{*}=$ dimensionless loss conductance of the space
$r_{s, 0}=$ the first term of the solar radiant time factors
$r_{n s, 0}=$ the first term of the nonsolar radiant time factors
$r_{s, 0, c}=$ the corrected first term of the solar radiant time factors
$r_{n s, 0, c}=$ the corrected first term of the nonsolar radiant time factors
Once the first terms of the two RTF series have been corrected, they are used as described in Chapter 7 (Equation 7.7) to determine cooling loads from the radiative heat gains.

## Example G. 1

Correction
Factor

As an example, consider the office used as an example in Section 8.2, with one significant modification: here, the double-pane windows have been replaced with single-pane windows. In order to determine the correction factor, we need to determine the $U A$ of the windows, the interior surface conductance of the windows, and the total room interior surface area.

- The window U-factor, for single-pane windows, may be determined by summing the resistances of the three layers:
- The exterior surface conductance for summer conditions from Table 3.4 is $4 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$ and the corresponding resistance is $0.25 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- The single pane of $1 / 4 \mathrm{in}$. glass, taking the conductivity as $6.9 \mathrm{Btu} \cdot \mathrm{in}$./ $\mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$ from Table 3.1, has a resistance of $0.036 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- The interior surface conductance, from Table 3.4 , is $1.46 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$, and the corresponding resistance is $0.68 \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$.
- The sum of the three resistances is $0.97 \mathrm{ft}^{2}{ }^{\circ} \mathrm{F} \cdot \mathrm{h} / \mathrm{Btu}$, and the U-factor is 1.03 Btu/h $\cdot \mathrm{ft}^{2}{ }^{\circ} \mathrm{F}$.

Table G. 1 Recommended Radiative/Convective Splits for Internal Heat Gains

| Heat Gain Type | Recommended <br> Radiative Fraction | Recommended <br> Convective Fraction |
| :--- | :---: | :---: | Comments

| Solar heat gain through <br> fenestration without interior shading | 0.9 | 0.1 |
| :--- | :---: | :---: |

Note: See Table 7.10 for all other heat gain types.

- The total window area, as given in Table 8.2 B , is $80 \mathrm{ft}^{2}$.
- The total interior surface area, including exterior walls, interior partitions, windows, ceiling, floor, and furniture, at or below the level of the dropped ceiling is approximately $804 \mathrm{ft}^{2}$.
The interior surface conductance for the windows is $1.46 \mathrm{Btu} / \mathrm{h} \cdot \mathrm{ft}^{2} \cdot{ }^{\circ} \mathrm{F}$; this was originally taken from Table 3.4 and used to find the U-factor for the window.

Using Equation G.1, with the understanding that both windows have the same U-factor and same interior conductance, so the window area is simply taken as the total window area, the dimensionless loss conductance is

$$
U^{*}=\frac{1.03}{1.46} \cdot \frac{80}{804}=0.070
$$

The dimensionless loss conductance is subtracted from the first value of the radiant time factors (RTFs). For this zone, the first value of the solar RTFs corresponding to the current hour is 0.53 ; rounding the dimensionless loss conductance to two decimal places, the new value is $0.53-0.07=0.463$. Likewise, the first value of the nonsolar RTFs is 0.51 , and subtracting the dimensionless loss conductance gives a value of 0.44 . In addition, the radiative fraction of the window solar heat gain is decreased to $90 \%$, as shown in Table G.1. When these three changes are made and the cooling load calculation is re-run, the peak cooling load is decreased by $4.0 \%$. The hourly cooling loads calculated with and without the correction for losses are shown in Figure G.1. The loads calculated without the correction are labeled Standard RTSM; those with the correction are labeled Improved RTSM.

The correction is not very significant with this amount of single-pane windows. This zone has two exposed façades, and $39 \%$ of the façade area is window. If the zone description is modified so that $95 \%$ of the façade area were glazed, the dimensionless loss conductance would increase to 0.173 . Using the correction factor would give a peak cooling load that was 12\% lower, as shown in Figure G.2.

Figure G. 1 Comparison of sensible cooling loads, with and without consideration of losses; $39 \%$ of the facade is glazed.

Figure G. 2 Comparison of sensible cooling loads, with and without consideration of losses; $95 \%$ of the facade is glazed.

## The Applications-Oriented Resource for Load Calculations

This new edition of Load Calculation Applications Manual presents two methods for calculating design cooling loads-the heat balance method (HBM) and the radiant time series method (RTSM)-in a thorough, applications-oriented approach that includes extensive step-by-step examples for the RTSM. Updates for this edition reflect changes in lighting, materials, and equipment used in buildings today, as well as new methods available since the first edition, including

- New internal heat gain data for office equipment
- New methods and data for the effects of internal shading on solar heat gains
- New data on heat gains from kitchen equipment, based on experimental measurements
- New weather data for more than 6000 stations worldwide
- A new ASHRAE clear-sky model, applicable worldwide
- Improved methods for generating design day temperature profiles
- A major revision of thermal properties data for building materials

This essential engineering reference begins with an overview of heat transfer processes in buildings and a discussion of how they are analyzed together to determine the HVAC load. Later chapters give in-depth coverage of the RTSM and HBM theory and application, systems and psychrometrics, and heating loads.

With this book comes access to spreadsheets for computing cooling loads with the RTSM and calculating the solar irradiation, conduction time factor series, and radiant time factors used in the method. The spreadsheets can be adapted to compute cooling loads for a wide range of buildings.

[^0]:    1. Cf. Incropera and DeWitt (2001).
    2. Even though heat transfer in an air gap is due to convection and radiation, it is approximated as being a conduction process with a fixed thermal resistance that is independent of the temperatures of the gap surfaces.
    3. Technically, conduction also occurs in liquids and gases, too. But here we are only concerned with conduction in solids.
    4. Appendix E covers the treatment of thermal bridges.

[^2]:    and H . = hemispherical SHGC
    ID \#s refer to U-factors in Table 4, except for products 49 and 50 .

[^3]:    ${ }^{\text {G }}$ Glazing cavity width equals original cavity width plus slat width.
    ${ }_{F} F_{R}$ is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

[^4]:    ${ }^{\text {G Glazing cavity width equals original cavity width plus slat width. }}{ }^{\mathrm{d}} F_{R}$ is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

[^5]:    a Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
    b Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to $0^{\circ}$.
    c Glazing cavity width equals original cavity width plus slat width.
    d FR is radiant fraction; ratio of radiative heat transfer to total heat
